*Experiments with cabbage.*—This is an account of a continuation of experiments of the previous year (E. S. R., 8, p. 689).

“The primary object of the cabbage experiment was to see if it is not possible to grow a larger number of good heads upon a given area where an abundance of water is applied at the right time by irrigation than is possible where the natural rainfall alone is depended upon. . . .

“The rows were all set 30 in. apart, and on one-half of the plat the plants were set 15 in. in the row and on the other 30 in. in the row, or at the rate of 13,939 and 6,969 plants per acre, respectively.”

The actual stand per acre was 12,030 plants in case of thick setting and 5,470 in case of thin setting.

“A larger percentage of plants headed on the more open stand and also a slightly larger percentage on the not irrigated land than on that irrigated.”

The cabbages were irrigated 4 times (July 21, August 3 and 10, and September 3), applying a little over 2 in. each time, or 8.25 in. in all.

The results per acre were as follows:

*Average weight per head and yield per acre of cabbages.*

	Firm heads.		Loose heads.		Leaves and stems (total).
	Average weight.	Total.	Average weight.	Total.	
Thin planting:	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
Irrigated .....	7.60	30,610	4.88	6,227	42,730
Not irrigated .....	6.95	29,480	4.23	4,624	49,220
Thick planting:					
Irrigated .....	5.13	46,590	3.23	7,688	64,100
Not irrigated .....	4.46	40,100	2.39	5,943	57,630

*The cost and profit of irrigation by pumping.*—An exact estimate of the cost of irrigation at the station could not be made because the plant was not used to its full capacity. Observations, however, showed that with a ton of coal costing \$4 the plant raised 0.9248 acre-inch of water each hour a distance of 26 ft. at a cost of 16.74 cts. per hour for fuel.

“With coal costing 16.74 cts. per hour, and charging 15 cts. per hour each for engine, engineer, and water distributor, the cost per acre-inch would be 66.76 cts.” Applying these figures to the above experiments it was found that “in spite of the very high cost of the water used there is still a decided balance in favor of irrigation in humid climates even for ordinary field crops such as corn (\$2.16 per acre), potatoes

(\$11.70), and hay." With cabbage the balance in favor of irrigation was \$2.43 in case of thin setting, \$29 in case of thick setting.

**The draft of corn harvesters**, F. H. KING and L. H. ADAMS (*Wisconsin Sta. Rpt. 1896*, pp. 205, 206, fig. 1).—Tests of the draft of the McCormick and Deering self-binding corn harvesters indicated that "the team working the Deering corn harvester was doing work equivalent to plowing a 12-inch furrow 4.6 in. deep and the other team a 12-inch furrow 6.6 in. deep."

"Each machine did its gathering and cutting very nicely, but the McCormick packed and tied its bundles much tighter than did the Deering, and in studying the results it must be kept in mind that on this account and because double the amount of corn per acre was cut by the McCormick the draft trials are in no sense comparable; neither were they intended to be; our object was simply to learn what work 2 horses were called upon to do with these machines as they were being worked."

**Comfortable low-cost barns**, F. E. EMERY (*North Carolina Sta. Bul. 112*, pp. 139-154, figs. 9).—Plans and specifications are given for 2 cheap small barns, a barn constructed by the State Geological Survey, a circular barn and yards for 30 cows, and the North Carolina Station farm barn. In addition some conveniences in feeding boxes and safe fastenings for doors are figured and described, and home-made cattle fastenings are illustrated and described.

**The uses of wood**, F. ROTH (*U. S. Dept. Agr. Yearbook 1896*, pp. 391-440, figs. 7).—Comparisons are made of the relative importance of wood and metals, of the differences in structure and composition of various kinds of wood in relation to strength, toughness, stiffness, weight, color, durability, fuel value, texture, etc. The uses of wood and the utilizing of timber are considered.

**Irrigation on the Great Plains**, F. H. NEWELL (*U. S. Dept. Agr. Yearbook 1896*, pp. 167-196, pls. 2, figs. 9).—The character and condition of the Great Plains and the need of irrigation in this region are briefly explained and the following topics are discussed in detail: Sources of water (streams, storm waters, and wells); methods of obtaining water (pumps, windmills, and steam and other engines); storing and conducting water (ponds, tanks, ditches, and flumes); applying water; duty of water; and cultivation.

**The sewage fields and the public milk supply of Paris** (*Rev. Sci. [Paris], 4. ser., 8 (1897), No. 14*, pp. 430-433).

**Experiments on water lifts**, A. CHATTERTON (*Agr. Ledger [India], 1897, No. 17*, pp. 16).—This is a report on comparative trials of 3 forms of water lifts in use in India for raising irrigation water.

**An instrument to aid in studying the wear of teams**, W. W. CARSON (*Univ. Sci. Mag. [Knoxville], 1897, No. 3*, pp. 5-21, pl. 1, figs. 5).—A description is given of a cheap instrument designed for a 2-horse team, which measures and records with tolerable accuracy (1) the distance traveled by the team, (2) the pull on each singletree at every point of that distance, (3) the grade, (4) the speed, and (5) the total work done on each singletree. Details of construction are given and numerous tests of accuracy are reported.

## STATISTICS—MISCELLANEOUS.

**Agricultural education and research in Belgium**, A. C. TRUE (*U. S. Dept. Agr. Yearbook 1896*, pp. 361-370).—This article describes the European vs. the American method of promoting education; gen-

eral characteristics of Belgian agriculture; the organization of agricultural education in Belgium—the higher institutions for education and research, the secondary schools, lecture courses for adult farmers, and primary education; agricultural societies; experiment station at Gembloux, and gives a comparative view of agricultural education in the United States.

"[The Belgian system] provides for primary, secondary, and superior schools or courses of agriculture. Primary agricultural courses for adult farmers are conducted under the direction of the ministry of agriculture, while courses of a similar grade for teachers and children are supervised by the ministry of public instruction. The secondary and superior schools of agriculture, as well as other agencies for promoting agricultural education and research, are directed by the ministry of agriculture."

After describing the work of these different grades of institutions the author says, in conclusion:

"In view of the strenuous efforts which European countries are making to give regular instruction in agriculture to large numbers of their rural population, it is well that our farmers should seriously consider their needs in this direction and the best ways in which these needs may be supplied. It is certain that the colleges of agriculture need to be strengthened and developed in order that the leaders in agricultural education, research, and progress in this country may be as thoroughly trained as they are in the Old World. The grade of instruction in these colleges needs to be raised rather than lowered, and it is not to be expected that these institutions will send back to the farms any considerable body of practical farmers. Their graduates will for the most part be needed as teachers, investigators, editors, officials, and managers of those agricultural industries in which scientific attainments are indispensable to success. If any considerable number of the farmers of the coming generations are to have definite instruction in agriculture, it must be in schools and courses specially devised to meet the needs of those who for any reason are unable to take the long and expensive college course. This article will have served its purpose if it contributes in any measure to an intelligent examination of the problems involved in providing a suitable system of agricultural education in this country."

**Reports of board of control and treasurer of Connecticut State Station, 1896** (*Connecticut State Sta. Rpt. 1896*, pp. XVI, 399-414).—This contains announcements relative to the publications of the station and to gratuitous chemical and botanical work of the station; a brief review of the work of the year by the secretary of the board of control; a financial report for the fiscal year ending September 30, 1896, and a comprehensive index.

**Tenth Annual Report of Illinois Station, 1897** (*Illinois Sta. Rpt. 1897*, pp. 18).—Lists of the bulletins published by the station and of experiments in hand during the year, and a detailed financial statement for the fiscal year ending June 30, 1897.

**Reports of director and treasurer of Wisconsin Station, 1896** (*Wisconsin Sta. Rpt. 1896*, pp. 1-9, 323-331, fig. 1).—A review of the year's work; lists of exchanges, acknowledgments, and of available publications of the station, and a financial statement for the fiscal year ending June 30, 1896.

**Seventh Annual Report of Wyoming Station, 1897** (*Wyoming Sta. Rpt. 1897*, pp. 22, *Append.* pp. 84).—Brief abstracts of the bulletins published during the year, plan of work at the station and substations, treasurer's report for the fiscal year ending June 30, 1897, and an appendix containing reprints of Press Bulletin 5 on Cooperative sugar-beet tests and of Bulletins 32 and 33 of the station.

**Yearbook of the Department of Agriculture, 1896** (*U. S. Dept. Agr. Yearbook 1896*, pp. 686, pls. 4, figs. 163, *dgms.* 9).—This includes a general report by the Secretary on the operations of the Department during the year; numerous semipopular

articles noted elsewhere, and an appendix containing notes on the organization of the Department, the agricultural colleges and experiment stations, agricultural statistics, composition of feeding stuffs and farm products, feeding standards, analyses of fertilizers, amount and value of barnyard manure produced by different farm animals, methods of controlling injurious insects, preparation and use of insecticides and fungicides, a cheap orchard spraying outfit, seed standards, hawks and owls, timber, lumber, and wood, irrigation, number, weight, and cost of grass seeds and the amount to sow per acre, metric system, Department publications, and a comprehensive index.

**Crop report for November, 1897** (*U. S. Dept. Agr., Division of Statistics Rpt. 154, n. ser., pp. 4*).—This gives preliminary estimates of the average yields per acre and average quality of certain crops in the United States, and a review of the forage crop situation with especial reference to wheat.

**Austria-Hungary as a factor in the world's grain trade; recent use of American wheat in that country**, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Circ. 19, pp. 23*).—This includes a report by United States Consul G. R. Ernst relative to the present wheat shortage in Austria-Hungary and the importation into that country of American grain, and statistics on the production and importation and exportation of wheat and other grains for the years 1886 to 1895, inclusive. The statistics show that "not only in the case of wheat, but also in that of the various other cereals, the tendency has been toward a larger home consumption of the national product and a consequent reduction of the surplus available for shipment to other lands. To such an extent have the exports declined and the imports increased that most of the cereals are now brought into the country in larger quantities than they are exported. Barley is the only grain of which any considerable amount continues to be shipped abroad."

**Exports of animals and their products**, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 17, pp. 3*).—This gives statistics relative to the exports of animals and animal products from the United States to all other countries and to the United Kingdom for the fiscal years 1889-'96.

**Synoptical index of the reports of the statistician, 1863 to 1895**, G. F. THOMPSON and G. W. HILL (*U. S. Dept. Agr., Division of Publications Bul. 2, pp. 258*).

**An ideal department of agriculture and industries**, E. TISSERAND (*U. S. Dept. Agr. Yearbook 1896, pp. 543-554*).—This is reprinted from the Report of the Recess Committee (House of Commons) on the Establishment of a Department of Agriculture and Industries for Ireland, London, 1897.

The author discusses the necessity for a department of agriculture, fundamental principles of a department of agriculture, methods of control in France, encouragement of private agricultural schools, cooperative agricultural experiments, securing scientific assistants, the scope of a department of agriculture, functions of an Irish department of agriculture, divisions of ministry of agriculture, qualifications of a minister and of heads of diverse consultative bodies, and permanent technical committees.

**Experiment stations, fields, and laboratories of the southwestern section of Russia and a plan of unification of their work**, YANOUSHEVSKI (*Zemledjelie, 1896, No. 13*).

**Agriculture in the Transcaspian region**, A. RODZEVITCH (*Selsk. Khoz. i Lyesor., 1896, No. 1*).

**Agriculture in Buenos Ayres** (*Mitt. Deut. Landw. Gesell., 12 (1897), No. 20, Suppl. pp. 113-120*).—The climate, soil, vegetation, and commerce of the province are discussed. Crop statistics are given.

**Agricultural calendar for Finland** (*Landbruks-kalender för Finland. Prepared by Landbruks styrelsen, Helsingfors, 1897, pp. 114*).—Gives a complete directory of the officers of agricultural educational and investigational institutions and agricultural and horticultural societies; regulations for the periodical Finnish butter exhibitions, and the various societies and associations for the advancement of Finnish agriculture.—F. W. WOLL.

## NOTES.

---

IOWA COLLEGE AND STATION.—James W. Wilson has resigned his position as assistant in animal husbandry in the college and station to become private secretary to the Secretary of Agriculture; and John A. Craig, formerly of the Wisconsin Station, has been elected to fill the vacancy.

MISSOURI COLLEGE AND STATION.—This college and station sustained a severe loss in the destruction by fire on November 8, 1897, of the residence occupied by H. J. Waters, dean of the college and director of the station. All the experimental records were saved. The insurance of \$5,000 practically covers the loss.

NEW YORK CORNELL STATION.—G. N. Lauman has been appointed assistant horticulturist of the station.

VERMONT COLLEGE AND STATION.—Hon. Crosby Miller, for 20 years trustee of the State Agricultural College and for 11 years member of the board of control of the station, died at Pomfret, Vermont, on November 22, 1897.

AMERICAN FORESTRY ASSOCIATION.—The first copy of the new organ of the Association, *The Forester*, formerly published by John Gifford, has been received. The Association has terminated its arrangement with the Pennsylvania Forestry Association by which the monthly publication of the latter, *Forest Leaves*, was recognized as the organ of the Association. The new journal "will contain not only popular articles and news of the forestry movement, and the like, but also technical articles of use to owners of woodlands, parks, grounds, and consumers of wood material." The number contains in addition to editorial and news items an account of the sixteenth annual meeting of the Association, held at Washington, D. C., December 8, 1897. This includes the address of the president of the Association; the report of the executive committee on Federal legislation, administrative action, forestry in Pennsylvania, tariff legislation, association meetings, publications, increase of membership, etc.; and the resolutions adopted. The officers for the ensuing year are: Francis H. Appleton, Boston, Mass., president; Sir H. G. Joly de Lotbiniere, Quebec, Canada, first vice-president; George C. McLanahan, vice-president for the District of Columbia; Frederick H. Newell, Washington, D. C., corresponding secretary; George P. Whittlesey, Washington, D. C., recording secretary and treasurer; and B. E. Fernow, F. V. Coville, Edward A. Bowers, D. M. Riordan, Gifford Pinchot, and Charles C. Binney, executive committee.

A STANDING COMMISSION FOR AGRICULTURAL EXPERIMENTATION IN HUNGARY.—The Hungarian Minister of Agriculture has created a permanent commission for agricultural experimentation, in which the different branches of agriculture are represented by practical men. This commission will outline a plan for the general work in the interest of agriculture, exercise a control over the same, and pass upon the subjects for special investigation.

PERSONAL MENTION.—J. B. Carruthers has been commissioned by the Planters' Association to study plant diseases in Ceylon.

J. G. Luchman, assistant to the late Baron von Mueller, has been appointed his successor and is now in charge of the National Herbarium at Melbourne, Australia.

Prof. A. Stutzer, director of the agricultural experiment station at Bonn, has been elected professor of agricultural chemistry and agricultural bacteriology at the University of Breslau. He will be accompanied by his present assistant, Dr. Hartle's.

Dr. Karl Müller, director of the agricultural experiment station at Hildesheim, died October 24, 1897, at the age of 50 years.

# EXPERIMENT STATION RECORD,

EDITED BY

	Page.
Editorial notes: Some unfortunate tendencies in station work .....	601
Agricultural education and research in the Scandinavian countries and Finland, F. W. Wool.....	605
Recent work in agricultural science .....	617
Notes .....	700

### SUBJECT LIST OF ABSTRACTS.

#### CHEMISTRY.

Reasons for the variation in the citrate solubility of Thomas slag meal, P. Wagner.....	617
Volumetric method for the determination of combined sulphuric acid, F. Mar- bontin and M. Molinié.....	617
The volumetric estimation of phosphoric acid .....	618
A new method of estimating fat in animal substances (preliminary notice), E. Bogdanow .....	618
The direct determination of calcium carbonate, F. Sestini.....	619
Application of hydrogen peroxid to the analysis of food stuffs, Lebbin.....	619
The determination of starch in the sweet potato, F. S. Shiver .....	619

#### BOTANY.

Studies of Mexican and Central American plants, J. N. Rose.....	623
An important function of leaves, U. Suzuki.....	621
On the behavior of active albumin as a reserve material during winter and spring, U. Suzuki.....	622

	Page.
On the physiological action of neutral sodium sulphite on phanerogams, K. Negami .....	622
The poisonous action of ammonium salts on plants, S. Takabayashi .....	622
Notes on the grasses and forage plants of Iowa, Nebraska, and Colorado, L. H. Pammel.....	623
Notes on the plants used by the Klamath Indians of Oregon, F. V. Coville....	623
FERMENTATION—BACTERIOLOGY.	
On the origin of sake yeast, K. Yabe .....	625
On the behavior of yeast at high temperature, T. Nakamura .....	626
Note on a grape wine fermented by sake yeast, K. Negami.....	626
Bromalbumin and its behavior toward microbes, O. Loew and S. Takabayashi.	627
METEOROLOGY.	
United States daily atmospheric survey, W. L. Moore .....	629
Report of the Chief of the Weather Bureau for 1897, W. L. Moore .....	630
Instructions for use of aneroid barographs on the Great Lakes, W. L. Moore..	630
Weather record for 1896 at Newport, Arkansas .....	630
WATER—SOILS.	
Soil moisture during the crop season of 1896, M. Whitney and R. S. Hosmer ...	630
Researches on the drainage waters of bare and cultivated soils, P. P. Dehérain.	631
Production of humus from manures, H. Snyder.....	632
Production of ammonia at the expense of organic matter and humus, E. Bréal.	633
Soil improvement, R. L. Bennett, G. B. Irby, and C. L. Newman.....	634
FERTILIZERS.	
The decomposition of nitrates by bacteria, A. Stutzer and H. Jensen.....	635
Fertilizers .....	636
Analyses of commercial fertilizers .....	638
Fertilizer analyses, B. H. Hite .....	638
The availability of organic nitrogen.....	637
FIELD CROPS.	
Cañaigre .....	643
Broom corn .....	643
The composition and yield of different varieties of sugar cane, P. Boname ....	638
The renewing of worn-out native prairie pastures, T. A. Williams.....	643
Report of the assistant in dairy husbandry, C. B. Lane .....	644
Experiments in breeding Noë summer wheat and Göttingen oats, Liebscher, Edler, and von Seelhorst .....	638
Wheat.....	639
Influence of the nature of soil on the culture of wheat .....	639

# EXPERIMENT STATION RECORD.

VOL. IX.

No. 7.

In the preparation of its annual report on the work and expenditures of the agricultural experiment stations this Office has recently made a review of the station publications received during the fiscal year ending June 30, 1897. Excluding annual reports which are wholly administrative documents containing neither accounts of station work nor practical information based thereon, 335 publications from the stations in the United States came to this Office during the past fiscal year. Of these, 98 were compiled bulletins of information and 47 recorded meteorological observations or fertilizer analyses. If we add the bulletins in which small experiments are made a sort of peg on which to hang a large amount of compiled data, it may safely be said that only about one-half of our station publications contain accounts of investigations regularly conducted by the stations with a view to extending the boundaries of our knowledge regarding the science and practice of agriculture. These statistics deserve serious attention chiefly from the fact that it is believed they represent a tendency in the experiment station enterprise in this country which unchecked will lead to very bad results. The rapid expansion of the experiment stations soon after the passage of the Hatch Act ten years ago made it almost necessary that a large amount of compiled information should be published in many States in order to lay the foundation for the intelligent understanding of the original work of the stations as soon as this had reached a state sufficiently advanced to warrant its publication for general distribution to farmers. It was supposed that by the time the new stations were really ready to publish their own work the necessity for compilations would have very largely passed away. But on the contrary the success of the stations has stimulated the demand for practical information, and the stations have increasingly yielded to the temptations to enlarge their popularity by sending out numerous bulletins of information even though these might be prepared at the expense of original investigations. So strong has been the influence in this direction that of late it has been seriously argued by some leading station workers that after all it should be the chief business of the stations to give the farmers such information as they need to aid them in improving their practice or defending themselves against ills common to their art.

A more subtle and, as we think, a more pernicious result of this tendency has been its effect on the investigations attempted by the stations. Many superficial experiments have been undertaken by the stations in response to the demand of farmers for results of immediate practical application. It is easy thus to give the impression that a large amount of work is being done at the station when really most of it may be of comparatively little value. Oftentimes experiments are tried in one line for a year or two and then something else is substituted as the popular demand shifts from time to time. As long as station workers dwell chiefly on the immediate practical needs of the farmers and listen only to their cries for help in this or that direction it is almost inevitable that their investigations will very largely follow so called practical lines and their methods of work keep dangerously close to those of the farmer. The strength of the movement for the practical education of the farmer, which during the past decade has been gathering head in the United States with wonderful rapidity, makes it all the more necessary that the experiment stations should carefully look into the future and should inquire with more diligence every year as to the proper limitations of their work. Clearly the trend of civilization is in the direction of specialized agencies for the performances of particular functions. It will be strange indeed if the agencies established for the express purpose of advancing the boundaries of knowledge regarding the science of agriculture as related to its practice can successfully follow any different path from that pursued by other similar institutions. How would the medical profession or even the general public regard the proposition that the specialists who, in their laboratories and hospitals are bearing almost the entire burden of establishing the principles and methods on which the practice of medicine is now making some real advance, should give up their researches for even half their time and devote themselves to writing popular treatises on the causes and remedies for prevalent diseases? They might thus perhaps save some valuable lives which will be lost because of ignorance of the present teachings of medical science, but who can not see that it is far better to keep these specialists at their work of investigation and try in other ways to widely disseminate the results of their researches.

It has sometimes been argued that the stations may profitably do a large amount of "demonstration" work, as distinguished from original investigation. If, however, such work once engages the attention of a station to any considerable extent, there is almost invariably a tendency to allow it to improperly encroach on the time and energy of station workers. It is so much easier to make a fair show in field, stable, or laboratory by doing over again what somebody else has taught us how to do well than to study, and plan, and toil to gain new truth. Demonstration of old truths belongs to the college and other educational agencies. It should never be more than an incident in the work of an experiment station. When our people are ready to supply the funds to maintain "demonstration fields," as is done in France

in numerous localities, they may easily become valuable adjuncts to the agricultural colleges and experiment stations. But when an experiment station descends from its high estate as an institution of original research to win favor by illustrating, on however large a scale, well-known facts and principles it sells its birthright for a very small consideration. It should ever be the chief business of the stations to give to American agriculture the new ideas which will give preeminence in the world's competition. Neither station officers nor farmers should be content to have the stations largely engrossed in doing anything less important than this.

The idea that the station workers may wisely pattern after successful farmers in organizing and conducting investigations is an especially mischievous one. It may be, as some have asserted, that in many important lines of farm work agricultural science is not at present able to suggest any way to improve the best present practice. But unless we believe that science has no hope of aiding the farmer, however thorough or far-reaching its researches may be, let us not disparage any honest effort to make scientific investigations in behalf of agriculture as thorough and rigid as is possible. As long as there is any expectation that further efforts properly directed may enable science to solve the hitherto inscrutable problems of agriculture let us devote ourselves heart and soul to the organization and prosecution of the most thorough investigations. If in any case the scientific structure thus far erected consist of facts of doubtful value or principles of uncertain origin, let us tear the whole thing down and begin over again with a greater devotion to truth. Fortunately the most severe criticism of agricultural science will reveal many facts and principles which can not be overthrown and which the best farmers would never have discovered by the ordinary methods of the farm. We need only to call to mind the wonderful advances in dairying under the stimulus of chemical and bacteriological investigations or the hopeful aspect of the researches on the utilization of the nitrogen of the air to show that all the signs of the times point to the highest practical achievements as the outcome of scientific work in behalf of agriculture if we will only devote ourselves earnestly and wisely to such efforts.

It may be that we need, on the other hand, to regard more scrupulously the necessary limits of scientific effort in behalf of agriculture. Certainly the comparatively meager results which have come from a vast number of field experiments of certain classes with crops and fertilizers should lead to the most careful consideration of the methods of such work. The continued large use of funds in this direction can hardly be justified unless it is possible to improve the methods of our investigations so as to give us greater confidence in the results. If it is clear to the experienced and scientific investigator of agricultural problems that the methods in common use in any line are based on false principles or that it is impossible to reach any definite conclusions by the best planned investigations in that line, it is his duty

to advise the experiment stations to withdraw from that branch of work. It is not right to lead the farmer to believe that science may aid him in any given direction when scientific men are themselves convinced that such a thing is impracticable. We need to have clearer distinctions drawn between science and pseudoscience as related to agriculture. But within the field in which it is agreed that science may reasonably work to aid the farmer—and this is a large and rapidly expanding area—let there be strict devotion to the truths and principles which science teaches and let us be done with the nonsense about imitating the practical man—who during countless past generations has not succeeded in advancing knowledge even with the rapidity of the traditional snail's pace. By adherence to his faith in the mission of science to agriculture the experiment station worker will most surely win the respect of the farmer and advance the highest interests of agricultural practice.

We believe that the time has come for the friends of the experiment stations in this country to declare themselves boldly in regard to the proper limitations of their work. The stations have a great fund intended for original research in behalf of agriculture. There is more need than ever before of scientific effort for the benefit of our agriculture and more promise than ever before of successful results from scientific investigations. The popularity of the stations has led to the practical diversion of much of their funds in the direction of pseudo-scientific effort and the dissemination of general information. It is time to call a halt. Make the stations what they were intended to be, institutions for original research. Man them with the best experts and hold these men to their legitimate work. Keep the fountains of new truth pure and bubbling, enlarge their capacity, guard them against defilement. In this way alone will the future of our agriculture be made secure.

# AGRICULTURAL EDUCATION AND RESEARCH IN THE SCANDINAVIAN COUNTRIES AND FINLAND.

F. W. WOLL,

*Assistant Professor of Agricultural Chemistry, University of Wisconsin.*

More than two-thirds of the territory occupied by the Scandinavian countries and Finland lies north of the sixtieth parallel, the latitude of Cape Farewell, the southern extremity of Greenland, and of Cape Chidley, the northernmost point of East Labrador. Thanks to the beneficent influence of the Gulf Stream on the climate of the European countries mentioned, conditions of life and industries are there of a wholly different character than what are found in the parts of America lying near or within the Arctic Circle. As a result, the Scandinavians rank among the foremost of civilized nations as regards both intellectual and material achievements. They have been able to vigorously attack the problems presenting themselves for solution and have offered valuable contributions to the progress of mankind. These countries early saw the benefits to be derived from technical instruction and investigation in agriculture and allied branches. Their system of agricultural education is highly developed and, in some of its phases, is not surpassed in other countries. A general inquiry into the methods of agricultural instruction in Scandinavia, and into the results of the research work done there in the line of agriculture, can not therefore fail to be of interest and may prove valuable to the student of agriculture.

In the summer of 1896 the writer visited a number of the Scandinavian and Finnish agricultural institutions of education and investigation, as a representative of the United States Department of Agriculture, and had good opportunities of becoming acquainted with these institutions, their working methods, and the men in charge. All the higher agricultural colleges of the countries mentioned were visited, and 6 agricultural elementary schools, 8 chemical control experiment stations, and 6 seed control stations. In other cases much information was gained by correspondence.

In this report the effort will be to give a comprehensive account of the system of agricultural instruction and investigation in the Scandinavian countries and Finland, and to bring forward its characteristic features. In order to convey some definite idea of the general condi-

tions of the countries, their areas, population, the importance of agriculture in them, etc., it may be well, at the outset, to give a few statistical data in this line. The figures given below and elsewhere in this report are from official sources and are the latest available in all cases:

*Area and population of Scandinavian countries.*

Country.	Area.	Population.	Population per square mile.	Rural population.
	<i>Sq. miles.</i>			<i>Per cent.</i>
Norway .....	124,445	2,000,917 (1890)	16.1	82
Sweden .....	172,876	4,873,183 (1894)	28.2	80
Denmark .....	15,289	2,185,335 (1890)	142.9	66
Finland .....	144,255	2,431,953 (1892)	16.9	90

Sweden, the largest of the four countries, is about the size of the State of California, or about twice as large as the State of Minnesota; and Denmark, the smallest of the Scandinavian countries, is a little larger than Maryland, or about half the size of South Carolina. Keeping these relations in mind, the following table, showing the number of institutions of agricultural instruction and research in Scandinavia, will prove of interest:

*Number of institutions for agricultural instruction and research.*

	Norway.	Sweden.	Denmark.	Finland.
<b>Educational institutions:</b>				
Agricultural colleges .....	1	2	1	1
Agricultural intermediate schools .....				2
Agricultural elementary schools .....	18	38	17	14
Dairy schools .....	10	16	3	17
Horticultural schools .....	3		3	4
Forestry schools .....	2		1	2
Ferriery schools .....		1		3
Total .....	34	57	25	43
<b>Institutions for investigation or control:</b>				
Chemical control stations .....	1	7	1	2
Milk control stations .....	3			
Seed control stations .....	3	19	1	2
Experiment stations .....	1	3	1	2
Total .....	8	29	3	6

The four countries have, on an average, an agricultural school for about every 58,000 of the rural population, and a control or experiment station for every 220,000 of the rural population. In order to reach a similar ratio in the United States there would have to be about 870 agricultural schools and 230 experiment stations; or, if the difference in the density of population (Scandinavian countries having 25.2 persons to the square mile and the United States 21.3) precludes comparison on this point, the State of Pennsylvania, with 117 persons to the square mile and 59.1 per cent rural population, should have 54 agricultural schools and 14 experiment stations.

The character of the land area of the four countries is indicated by the data presented in the following table:

*Productive area, forest area, etc.*

Country.	Productive area.	Forest area.	Under cultivation.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Norway.....	28.9	24.0	<i>a</i> 2.8
Sweden.....	56.7	44.4	8.2
Denmark.....	90.7	4.7	44.5
Finland.....	65.4	57.4	3.0

*a* Pastures and meadows, 2.1 per cent.

The greater portion of the farm land is owned by small holders in all four countries, as will be readily observed from the following statement, which also includes other information illustrating the agricultural conditions of the Scandinavian countries:

*Agricultural statistics.*

Country.	Number of farms.	Farms under 20 hectares (50 acres).	Per 100 inhabitants.		
			Acreege of cereal crops.	Number of milch cows.	Agricultural capital, 1888.
Norway.....	146,355	93.8	25	35	\$315
Sweden.....	329,593	86.0	80	34	310
Denmark.....	233,037	87.4	150	46	685
Finland.....	114,769	<i>a</i> 77.8	66	39	175

*a* Under 25 hectares.

AGRICULTURAL EDUCATIONAL INSTITUTIONS.

The system of agricultural education in the Scandinavian countries and Finland is arranged along two distinct lines, viz, elementary and higher instruction. The schools providing elementary instruction in agriculture are located in different parts of the country and are supported largely, though seldom wholly, by State aid, the districts in which the schools are located (*amt, län, stift*) paying the remaining portion of the expense. In Norway the State generally contributes three-fourths of the expenses to the support of the elementary schools, while in the neighboring countries a definite sum of money, ranging from 1,000 to 10,000 crowns (1 crown=26.8 cents) or more, is appropriated annually for their support. The institutions offering higher instruction in agricultural branches are supported wholly by the respective States.

The elementary schools provide both practical and theoretical instruction (the Swedish *landtmanna* schools excepted, to which reference will be made below), while the higher agricultural schools are essentially theoretical, previous experience in ordinary farm work being required of students.

In addition to these two kinds of schools, Finland has two intermediate schools, with courses of instruction corresponding to some extent to the German *Mittel-schule*. There are, however, a number of schools in the Scandinavian countries, classed as elementary, which give equally as advanced courses as these two Finnish middle schools.

The elementary agricultural schools of the different countries will be considered first.

#### ELEMENTARY AGRICULTURAL SCHOOLS.

Since the organization and the plan of instruction of these schools do not differ greatly in the four countries under consideration, the differences found being of minor importance, the more prominent features of the system as seen in operation in one country, *e. g.*, Norway, will be given, with briefer reference to the schools of the other countries, pointing out any characteristics worthy of special notice.

*Elementary agricultural schools in Norway.*—The instruction given in the elementary agricultural schools of Norway is built upon common school education, the aim being “to impart fundamental knowledge in agricultural branches to future farmers.” To be admitted as a pupil the candidate must be 18 years of age, must produce a doctor’s certificate that he is strong, without bodily defects, and free from contagious disease, and a certificate of character from his pastor. He must be able to write fairly correctly from dictation, be efficient in plain arithmetic, and have a fair knowledge of geography and the history of their country. At least one year’s practice in ordinary farm work is required, and an application, written by the candidate himself, is to be sent to the director of the school. The candidates must finally pass an entrance examination in composition, arithmetic, geography, and history before being admitted as pupils. Preference is given to applicants living in the district where the school is located (which partly supports the school) and to eldest sons owning allodial rights, who therefore may be counted on settling as farmers in the district.

The number of students who can be accommodated in one of these elementary agricultural schools varies from 12 to nearly 100, the average number being about 27. The total registration of the schools during 1895-’96 was over 450. As the number of applicants always greatly exceeds the number that can be accommodated, only those well qualified for the work of the school and who intend to become farmers in the district in which the school is located, are as a rule likely to be admitted.

The schools are located in the country on farms belonging to the respective districts (counties) and operated at their expense. In a few cases the director or principal has no salary except the proceeds from the farm sales, and in such cases he is allowed to sell only animal products—no grain, hay, or straw. The farms vary in size from 100 to 200 acres or more. They are generally well equipped with buildings, farm machinery, library, instructional apparatus, improved stock, etc.

The director must be a practical farmer. He usually holds a diploma from the agricultural college at Aas, and often he has continued his studies abroad, along special lines, after graduation. It is required of him to conduct the farm so that it forms a good object lesson and a model, both for the pupils themselves and for the farmers of the surrounding district.

The number of teachers at the schools, in addition to the director, varies somewhat according to the development and conditions of agriculture in the various districts. There is generally a "second teacher," who is the assistant of the director, and teachers in horticulture, forestry, and dairying. The latter are experts in their particular lines, and teach only these branches, while the general fundamental branches are taught by the director and the "second teacher."

The course of instruction offered in these schools is partly theoretical, partly practical, and lasts one and a half or two years. The theoretical branches are taught during the winter months, viz, from October to April; the practical work then commences and runs through the summer until after the harvest. There is generally a vacation of three weeks or a month after haying and two weeks' vacation at Christmas. The theoretical instruction occupies three hours a day and covers the following preparatory studies: Composition, practical arithmetic, plain geometry, chemistry, and physics. The basal studies taught are agriculture (including mineralogy, geology, botany, and physiology), animal husbandry (including dairying), forestry, horticulture, book-keeping, and farm accounts. Practical exercises are given in surveying, map drawing, farm machinery and farm buildings, drainage, forestry, horticulture, blacksmithing and carpentry, and geological and botanical excursions. Practical work in the field or barn occupies the full time of the students during the summer, when they take part in the regular farm work under the supervision of the director or the second teacher. The work in blacksmithing and carpentry comes throughout the year by rotation, one or two students at a time having exercises in these branches each day or afternoon. The class-room instruction consists largely of recitations from text books, and written compositions on the subjects treated are frequently required.

The students as a rule pay a small fee for tuition, room, and board, ranging from 100 to 300 crowns (\$26.80 to \$80.40) a year. This fee covers all expenses except for books and stationery. The different counties provide a number of full or half scholarships ("free seats") for poor, worthy scholars, or give stipends to such scholars amounting to the tuition fee or more. The number of "free seats" varies in the different schools. Often 3 or 4 in a class of 20 have free tuition, sometimes 10 or 12. As a general rule, a distinction is made between students from the district supporting the school in part and outsiders. The former pay only for board and lodging (about \$26.80 a year), while others, special or private students, pay a tuition fee in addition. The students do not receive any pecuniary compensation for their work on the farm during the summer or at other times.

At the completion of the full course, the students are subjected to written and verbal examinations—the former in agriculture, animal husbandry, and practical arithmetic; the latter in agriculture and botany, animal husbandry, forestry and horticulture, chemistry and physics, practical arithmetic and geometry. The pupil is marked in each study, and on passing the examination and properly completing the course receives a diploma from the school, giving in detail his standing in each study and his average standing, together with remarks on his industry and behavior during his school life. The diploma is signed by all the teachers and the “censors” (special examiners appointed by the board of regents of the school to conduct the examinations in conjunction with the teachers).

The following list of elementary agricultural schools in Norway is complete up to date (January, 1897). As previously stated, the schools are supported partly by the State and partly by the local district (*amt*). The school at Bodö in the northern part of Norway forms an exception to this rule, being supported by the State alone, the salary of the teachers and all expenses of 20 pupils, 10 from Nordland and 5 each from Finmarken and Tromsö *amt*, being provided for by State appropriation. Other pupils of this school have free tuition and rooms, lighted and heated, but pay 26 crowns (\$7.03) per month for board.

<sup>a</sup> Private theoretical school.

*Elementary agricultural schools in Sweden.*—The lower agricultural schools of Sweden are of two kinds, so-called *landtbruksskolor* (agricultural schools) and *landtmannaskolor* (farmer schools). The former resemble the elementary agricultural schools of Norway in giving both practical and theoretical instruction, while the latter are purely theoretical and correspond in some measure to our American short courses in agriculture.

The objects of the *landbruksskolor* are "to give practical experience in the performance, planning, and supervision of farm work, and to offer instruction in the fundamental principles underlying farm practice." They are therefore primarily practical schools. The courses last two years, beginning on the first day of November and continuing throughout the year. The practical instruction consists in participation in all kinds of farm work in the field, stable, barn, and blacksmith and carpenter shops. In this work the second-year students act as foremen, keeping journals of the work done under their direction and also taking part in the work themselves, as is the usual practice with foremen on Swedish farms. The theoretical instruction covers the following subjects: Composition, arithmetic, drawing, geometry, natural history, agriculture, animal husbandry, dairying, forestry, horticulture, and farm bookkeeping. This instruction is given during the winter months, four to five hours daily. The average number of hours of theoretical instruction during the year was in 1895, for first-year students, 347 hours; for second-year students, 679 hours, the number ranging at the different schools between 207 and 466 hours for the first-year students, and between 486 and 868 hours for second-year students.

Students must be at least 18 years of age on entering the schools, and must have similar qualifications to those required by the elementary schools of Norway. The average age of students entering these schools is, however, considerably higher than the limit set, being between 22 and 23 years. On passing the final examinations and otherwise successfully completing the course the students receive diplomas from the school.

The Swedish *landbruksskolor* were established in 1840. They are supported in part by a Government appropriation of 4,000 crowns (\$1,072) each, or where more than one school is held inside of a county (*län*), 2,000 crowns to each of the others, on condition that the agricultural society or county board appropriate a similar amount. There are at present 24 schools of this kind, 20 of which receive 4,000 crowns each and the remainder 2,000 crowns annually.

The second class of elementary agricultural schools, *landtmannaskolor* (farmer schools) are calculated to furnish young men with the theoretical agricultural education required for the proper management of smaller farms. The courses last 20 to 24 weeks, beginning on the last week day of October each year. The requirements for admission are somewhat higher than those of the practical schools, and in addition at least one year's experience in ordinary farm work is required. The studies taught in these schools are physics and meteorology, chemistry, botany, zoology, geology, agriculture, veterinary science, animal husbandry, dairying, architecture, geometry and surveying, farm bookkeeping, and drawing. On passing the final examinations the pupils receive a diploma signed by the principal of the school. The total number of hours of instruction during the course varied in 1895 from

595 to 1,001 at the different schools, or an average of 4 to 7 hours a day. The average total number of hours of instruction was 825, equivalent to 6 hours daily instruction.

The *landtmanna* schools were established in 1887. They receive 3,000 crowns (\$804) annually from the Government on condition that a similar amount be granted by the county in which the school is located, that the plan of instruction be approved by the Government, and that one pupil for each thousand crowns granted by the Government be given a full scholarship, including tuition, board, and room rent. There are at present 14 of these agricultural schools in operation in Sweden.

The following statement shows the location of the Swedish elementary agricultural schools in operation during 1894-'95, with the number of students attending each school. The total enrollment of students was 527, and the average attendance was 14.4 for the *landtbruks* schools and 13 for the *landtmanna* schools.

*Elementary agricultural schools in Denmark.*—The number of elementary agricultural schools in Denmark at the present time is 17. They are supported in part by small grants from the State and by the various agricultural societies, and are all private schools deriving their main income from tuition fees. At the larger and older of these institutions scholarships are provided, as a rule through private munificence, enabling poor and worthy pupils to frequent the schools as well as those in better circumstances.

The history of the oldest elementary agricultural school in Denmark, the Classen Agricultural School at Näsgaard, Falster, is remarkable

from the fact that it was ready to receive pupils nearly 50 years before the constituency for whose benefit the school was established availed themselves of its facilities. The school was founded through the generosity of a Danish major-general, J. F. Classen (who died in 1792). His will contained a clause providing for the establishment of a seminary or agricultural institute for the benefit of "good subjects" of the farming class, where fundamental agricultural principles were to be taught during a course of from 3 to 4 years. The scholars were to have free rooms and board, and also the necessary cloth (*wadmol*) and muslin for wearing apparel. They were to be elected from the different parts of the country, on recommendation of the county magistrates. The agricultural society was asked to select a person who should fit himself for the professorship in agriculture at this school through 3 years' of travel in foreign countries. In 1793, a surveyor, Mr. Olufsen, was elected to the position; and he traveled through most of the European countries during the following years. On his return to Denmark he at once proceeded, in conjunction with the board of regents of the school and the State agricultural society, to carefully plan, build, and equip the school at Näsgaard, on the island of Falster, located in a beautiful region peculiarly well adapted for the purpose in view. The school was ready for occupancy in the summer of 1800, being the first of its kind in Denmark, and, as far as is known, in the world. (The agricultural school at Hofwyl, Switzerland, was founded in 1806.) Only one pupil presented himself, however, and the school could not be opened. "The farmers did not believe that anything could be gained by going to a school to learn how to run a farm." Two years later, no farmers' sons having applied for admission, the school was opened to other than farmers' sons. The equipment of the school was greatly strengthened by the addition of a farm of about 40 acres; and experimental plats, a botanical garden, fish ponds, orchards, etc., were planned and laid out. But in spite of all efforts no pupils could be induced to take advantage of the opportunities offered, and Professor Olufsen went to Copenhagen, where he met with considerable success as a lecturer on agricultural economics at the Classen Library. The school building, with the farm, was rented for a number of years, and later was operated as an experimental farm for studying problems in breeding horses, cattle, sheep, and swine.

With the development of the natural sciences and the gradual awakening of the European farming classes in the second quarter of this century, the time finally came when the school could be opened, pupils presenting themselves in 1849 through the efforts of leading patriotic Danish gentlemen. Since this time it has been in operation and has been regularly frequented by the limited number of students which can be accommodated. The course of study laid out covers two years, 9 students being admitted each year, or 18 in all. The total number of students that have gone through the school up to date is 431.

The instruction during the first year covers composition, arithmetic, mathematics, biology and botany, chemistry, physics, and dairying; and during the second year, animal husbandry (anatomy, breeding, and feeding), agriculture, agricultural physics, economic botany, farm machinery, dairying, veterinary science, farm bookkeeping, written exercises, drawing, and surveying. There are 3 regular teachers and 1 extra teacher connected with the school. The theoretical instruction occupies 3 hours daily, with practical exercises in field work in the afternoon.

There are several other elementary agricultural schools in Denmark, as shown by the following table, which contains information concerning their establishment, courses, total and average number of students, etc.:

*Main elementary agricultural schools of Denmark (1895).*

Name.	Location.	District ( <i>amt</i> ).	Year established.	Length of courses.	Total number of students.	Average number of students per year.
Classen ....	Näsgaard.	Lolland and Falster ..	1849	2 years' course with 9 months each year.	431	18
Odense ....	Odense ...	Fyn .....	1855	9 months .....	1,030	26
Lyngby ...	Lyngby ..	Seeland.....	1867	6 and 10 months .....	2,434	107
Tune .....	Taastrup ..	do .....	1871	6 and 9 months .....	3,037	74
Ladelund ..	Brörup ..	Jutland.....	1879	5 months .....	1,663	103
Dalum.....	Odense ...	Fyn .....	1886	6 months .....	a 849	106
Malling....	Malling...	Jutland.....	1889	6, 9, and 12 months .....	b 265	36
<i>a</i> Agricultural.			<i>b</i> Dairying.			

Other agricultural schools are in operation at Lumby (established in 1858), Emdrupborg (1874), Faurbogaard (1875), Vinding (1878), Greisdalen (1879), Morsö (1884), Klank (1885), Yding (1889), Graneli, Aarup, and Oddense.

The number of young farmers who have received instruction in these schools up to the present time doubtless considerably exceeds 10,600. This is a remarkable showing, considering that the total population is only a little more than two million people (farming population, one and one-third million), and that it is less than 50 years since the first school began its work. The elementary agricultural schools of Denmark have of late years been frequented by more than 500 students annually, nearly all of whom are sons of Danish farmers and have chosen farming as their occupation.

*Elementary agricultural schools in Finland.*—As stated in the introduction, Finland has two intermediate agricultural schools, Kronoborg Agricultural Institute and Hajus Agricultural School. The former was established in 1874. Two different courses in agriculture are offered, one lasting 2 years and the other 1 year. A dairy course is also given. The Government grants scholarships to 20 pupils. Other students pay 20 marks (\$4) a month for lodging and board. During 1893-'94 the institute was attended by 43 students in the 2 years' course, 11 in the 1 year course, and 14 in the dairy course, a total of 68 students. The instruction offered is both theoretical and practical. In 1893-'94 the

following number of hours were given up to the various studies in the 2 years' course: First year—natural history, 122; arithmetic, 153; composition, 259; total, 534; second year—natural history, 30; arithmetic, 86; composition, 57; agriculture, 134; animal husbandry, 50; veterinary science, 65; farriery, 9; drawing, 40; forestry, 30; surveying, 65; agricultural law, 18; farm bookkeeping, 76; total, 660.

In addition the students took part in all practical work on the farm, in the field, barn, and stable, composting manure, threshing, tile-draining, grubbing, gardening, harvesting ice, road repairing, forestry work, etc., equivalent to 13,560 hours work for one man.

The faculty is composed of a director, a veterinarian, and a "third teacher," besides registrar, bookkeeper, farm superintendent, dairy-woman, mechanic, and gardener. The estate consists of about 5,000 acres, 1,200 of which are under cultivation and 110 acres in pastures. The students are in general graduates of the Finnish common schools or high schools.

The second intermediate agricultural school in Finland, at Harjus, was opened for instruction in 1889. Like the preceding school it has 2 distinct departments, a semi-elementary course in agriculture lasting 2 years, and a theoretical winter course running through 2 seasons. Twenty scholarships are offered in the former course and additional pupils are accepted up to the capacity of the school, 36 being in attendance in 1893-'94. The winter course was frequented by 34 pupils during the same year. This course is limited to 40 pupils, all of whom have free instruction, rooms, and board. The plan of instruction given is more along theoretical lines and is more advanced than that followed at the elementary agricultural schools.

The daily program of these schools is interesting. At Kronoborg the recitations in the 2 year course are held from 6 to 8 o'clock in the morning and evening during the winter semester and during a few weeks in October. At Harjus the plan is as follows: 5 a. m., rising hour; 6 to 8, recitations; 8 to 9, breakfast; 9 to 2 p. m., practical farm or dairy work; 2 to 3, dinner; 3 to 6, study hours; 6 to 8, recitations; 8 to 9, supper; 10, bed time. The students working in the cow or horse stable, this work coming by rotation, rise at 4 a. m. In summer all the students rise at 4 a. m., begin work at 5 a. m., and finish work at 8 p. m., having 2 hours for meals and retiring at 10 p. m.

A third school with similar plan of instruction is held at Mustiala Agricultural Institute, being a distinct department thereof. This school will be referred to later.

These schools, as most other Finnish agricultural educational institutions, for a number of years past have been entirely unable to accommodate all the young men who have applied for admission. The number of applicants for 203 places in 1893-'94 was 572; in single instances the number applying for admission was five times the number that could be accommodated. To provide for this larger number of students, 6

elementary agricultural schools are now under organization, and provisions have been made for the establishment of 5 additional schools of this kind. When these latter have been established, there will thus be 22 elementary agricultural schools in operation in Finland. The following table gives statistics of those now in operation:

*Statistics of intermediate and elementary agricultural schools of Finland, 1893-'94.*

Location.	Number of students.	Year established.	State appropriation.	
			Regular.	1893-'94.
Mustiala, lower department <i>a</i> .....	34	1840	\$13,912	\$20,319
Kronoborg.....	51	1874	4,632	9,910
Harjus.....	70	1889	5,365	9,206
Söderkulla.....	25	1863	2,316	2,316
Tuorla.....	18	1885	1,853	1,853

Tarvaala.....	17	1867	1,853	1,853
Orisberg.....	16	1885	1,853	2,123
Koivikko.....	18	1853	1,158	1,158
Haga.....	9	1888	1,853	1,853
Total.....	352	.....	44,523	67,278

*a* The appropriation given is for Mustiala Agricultural and Dairy Institute.

Seven of the schools given in the preceding table are held on estates or large farms belonging to the Crown, the rest on farms belonging to private individuals. In either case the regular annual appropriation for each elementary school is 9,600 marks (about \$1,800), except in special instances where the amount is increased to 12,000 marks (\$2,300). The total appropriation for agricultural schools in Finland for the year 1893-'94 approached 350,000 marks, or about \$70,000.

[Concluded in next number.]

## RECENT WORK IN AGRICULTURAL SCIENCE.

### CHEMISTRY.

**Reasons for the variation in the citrate solubility of Thomas slag meal,** P. WAGNER (*Landw. Vers. Stat.*, 49 (1897), No. 3, pp. 227-230).—Büeking and Linek have found<sup>1</sup> in Thomas slags three distinct minerals, one with hexagonal crystals resembling apatite, another with bluish monoclinic crystals of the formula  $4\text{Ca}_3\text{P}_2\text{O}_8 + 3\text{Ca}_3\text{SiO}_5$ , and a third with yellowish rhombic crystals with the approximate formula  $\text{Ca}_4\text{P}_2\text{O}_9$ . These contain 36.8, 31.2, and 38.8 per cent of  $\text{P}_2\text{O}_5$ , respectively. The author has isolated these different minerals and determined the citrate solubility of each. He finds that 85.42 per cent of the  $\text{P}_2\text{O}_5$  of the bluish crystals is soluble, 88.75 per cent of the yellow, and about 60 per cent of the apatite-like substance. He suggests that these differences in solubility may partially explain the variations noticed in the solubility of the phosphoric acid of different slags.—J. P. STREET.

**Volumetric method for the determination of combined sulphuric acid,** F. MARBOUTIN and M. MOLINIÉ (*Bul. Soc. Chim. Paris*, 3. ser., 17 (1897), No. 22, pp. 950-955).—This method, which is adapted to the analysis of water, is as follows: Acidulate 100 cc. of the water with hydrochloric acid and boil to drive off carbon dioxide. Add, drop by drop, 30 cc. of barium chlorid, maintaining the temperature of the solution meanwhile near the boiling point, and afterwards keep in an oven at about  $40^\circ$  until the precipitate has settled. Neutralize with a few drops of ammonia and add 30 cc. of potassium chromate. Heat slightly, and after cooling make the volume to 300 cc. To 100 cc. of the clear liquid add 2 cc. of sulphuric acid (1:4) and 5 cc. of arsenious acid solution, heat gently, and stir until color disappears. Neutralize with potassium carbonate and run in standard iodid solution until the blue coloration appears on testing with starch. The following equation is given, in which  $t$ =mg. of iodid in 1 cc. of the iodid solution;  $n$ =cc. of iodid solution required by each 100 cc. of distilled water;  $n'$ =cc. of iodid solution required by 100 cc. of the water tested, and  $x$ =mg. of sulphuric anhydrid in a liter of water:

$$x = 10 (n - n') 3t \frac{3 \times 4 \times 127}{4 \times 80}.$$

If the iodid solution is exactly fiftieth normal (1 cc.=2.54 mg. of iodid) then

$$x = 16 (n - n').$$

<sup>1</sup> Ztschr. Stahl u. Eisen 1887, p. 245.

The reactions which occur are as follows:

The solutions used are as follows: Crystallized barium chlorid 4.8 gm. per liter, crystallized potassium chromate 3.9 gm. per liter, arsenious acid (dissolved in 10 gm. of potash, afterwards slightly acidulating with sulphuric acid) 4.95 gm. per liter.

**The volumetric estimation of phosphoric acid** (*New Jersey Stas. Rpt. 1896, pp. 118-121*).—The results of comparisons of the official method and of a modification of Kilgore's volumetric method<sup>1</sup> on 276 samples of complete fertilizers are reported. The volumetric method used is described as follows:

"Weigh 2 gm. of material into a porcelain crucible, evaporate with 3 cc. of magnesium nitrate, ignite and dissolve in hydrochloric acid. To an aliquot part of this solution (0.25 gm.) add 5 cc. of concentrated nitric acid, neutralize with ammonia, and clear with a few drops of nitric acid. Heat on the water bath to 60 to 65° C., add 50 cc. of freshly filtered molybdic solution for each decigram of phosphorus anhydrid present, and digest at the same temperature for 15 to 20 minutes.

"Decant the clear liquid on a filter as quickly as possible (a plain filter without suction). Wash the precipitate by decantation twice with the nitric acid solution, once with the potassium or ammonium nitrate solution, and transfer it to the filter and wash with 150 cc. of cold water. Wash the precipitate with the filter into the beaker, add an excess of the standard potassium hydroxid solution and a few drops of the phenolphthalein solution, and titrate the excess of alkali by adding the standard nitric acid solution until the color disappears. The number of cubic centimeters of alkali used, less the number of cubic centimeters of acid necessary to neutralize the solution, is equal to the number of milligrams of phosphorous anhydrid present."

The reagents used were in all cases the same as those recommended by Kilgore. The total percentage of phosphoric acid found by the official and the volumetric methods are tabulated.

"The results secured were extremely satisfactory, the average results by the volumetric method being 10.72 per cent against 10.70 per cent by the official method. Of these results, 150 were higher by the volumetric, 113 lower, and 13 identical with the official method; the greatest variation was 0.16 per cent, and 114 samples varied less than 0.05 per cent."

**A new method of estimating fat in animal substances (preliminary notice)**, E. BOGDANOW (*Arch. Physiol. [Pflüger]*, 68 (1897), No. 8-9, pp. 431-433).—It was found that when meat which had been extracted with ether was boiled with alcohol considerable material was dissolved, which on evaporating the alcohol was easily soluble in ether. By extraction with ether alone 6.65 per cent of the total dry matter of a sample of meat was removed. When a sample of the same meat was treated with ether until practically as much fat as possible had been removed and then boiled with alcohol, the alcohol evaporated and the residue extracted with ether, a total amount of fat equaling 11.486 per

<sup>1</sup>U. S. Dept. Agr., Division of Chemistry Bul. 46. p. 13; North Carolina Sta. Bul. 140 (E. S. R., 9, p. 416).

cent of the dry matter of the meat was obtained. The material extracted by the alcohol is not insoluble in ether, but in the author's opinion is intimately mixed with some matter not affected by the ether, but which the alcohol removes.

**The direct determination of calcium carbonate,** F. SESTINI (*Ann. Agron.*, 23 (1897), No. 7, pp. 326, 327).—Digest 5 gm. fine soil in 100 cc. of 0.5 per cent acetic acid at the boiling point, in a flask with reflux condenser, until evolution of carbon dioxide is complete (about 1 hour). Cool, filter, and evaporate 55 cc. of the filtrate to 5 cc. Add hydrochloric acid (sp. gr. 1.1) and evaporate, repeating the operation until the acetic acid is all driven off and the acetates are converted into chlorids. Dissolve the residue from the evaporation in a small quantity of water, add 10 cc. of ammoniacal ammonium chlorid and make up to 55 cc., with 75 per cent alcohol. Filter to remove calcium sulphate, etc., and precipitate lime in 50 cc. of the filtrate with neutral ammonium carbonate, or, better, ammoniacal oxalate.

**Application of hydrogen peroxid to the analysis of food stuffs,** LEBBIN (*Pharm. Ztg.*, 17 (1897); *abs. in Analyst*, 22 (1897), Nov., p. 289).—The author calls attention to the solvent power of hydrogen peroxid on starch, and reports some experiments on this. Attempts to estimate starch in this way do not appear to have given satisfactory results as yet. The reagent has been found useful in rendering material starch free for microscopical examination, as the appearance of the cellulose structure is unaltered. This has been found serviceable in distinguishing wheat flour from rye flour and also in detecting ergot in flour.

The author's method for the estimation of crude fiber by means of hydrogen peroxid has been described (*E. S. R.*, 8, p. 857).

**The determination of starch in the sweet potato,** F. S. SHIVER (*South Carolina Sta. Bul.* 30, pp. 11).—Several well-known methods for determining starch are described and comparative studies with them reported. A volumetric method for the determination of the reduced copper with potassium permanganate was compared with the gravimetric method, with results "as concordant as could be expected, the difference in the average between the two being only 0.0005 gm. of copper." Comparisons were made on a number of varieties of the sweet potato of the Sachsse method (inversion with acid), the modified Reinke method (treatment with malt extract without pressure), the Maercker method (treatment with malt extract and heated under pressure with tartaric acid), and the Honig method (heating with glycerin). The results of the comparisons are summarized in the following table:

*Comparative determination of starch in sweet potatoes.*

Method.	Southern Queen.	Red Bermuda.	General Grant.	White Bermuda.	Georgia yams.	Yellow Jersey.	Bunch yams.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Sachsse .....	27.36	28.00	26.12	23.74	27.32	25.20	26.42
Reinke (modified) .....	25.29	26.86	23.93	21.31	25.77	22.73	.....
Maercker (second) .....	25.14	26.66	.....	.....	25.88	.....	.....
Honig .....	24.45	25.98	.....	22.34	25.23	.....	.....

"In view of all the work done on the determination of starch in the sweet potato, the Reinke method and Maereker's method are to be recommended, and of these the first is perhaps the best. . . .

"Asboth's method, which consists in precipitating the starch with a standard solution of barium hydrate, and then determining the excess of barium hydrate with standard acid, was tried, but the results were exceedingly unsatisfactory, so much so that I do not consider the results worth reporting."

**On the chemical properties of diastase and the occurrence of araban in diastase preparations, A. WRÓBLEWSKI** (*Ber. Dent. Chem. Gesell.*, 30 (1897), p. 2289; *abs. in Chem. Ztg.*, 21 (1897), No. 93, *Repert.*, p. 282).

**The estimation of carbonic acid in natural waters, C. A. SEYLER** (*Analyst*, 22 (1897), Dec., pp. 312-319).

**The exact estimation of total carbohydrates in acid hydrolyzed starch products. G. W. ROLFE and W. A. FAXON** (*Jour. Amer. Chem. Soc.*, 19 (1897), No. 9, pp. 698-703, figs. 2).—The authors give a formula for correcting the specific gravity when specific rotatory power is known, factors, etc., and various tests of the accuracy of these.

**A contribution to the spontaneous combustion of vegetable food and feeding stuffs, F. HOFFMANN** (*Wchnschr. Brau.*, 14 (1897), p. 437; *abs. in Chem. Ztg.*, 21 (1897), No. 85, *Repert.*, p. 233).

**Mechanical arrangement of fat-extraction apparatus, G. J. VOLCKENING** (*Jour. Amer. Chem. Soc.*, 19 (1897), No. 9, pp. 735-738, fig. 1).—This shows the arrangement of sets of fat-extraction apparatus, generation of steam for heating the ether, etc.

**On the determination of dry matter in peat, H. TRYLLER** (*Landw. Vers. Stat.*, 49 (1897), No. 1-2, pp. 145-161, fig. 1).—A discussion of the method, with the results of a large number of determinations.

**On the speed of reduction of ferric alum by sugar, J. H. LONG** (*Jour. Amer. Chem. Soc.*, 19 (1897), No. 9, pp. 683-698).

**On the determination of calcium, aluminum, and iron in phosphates, L. LINDET** (*Ann. Chim. Analyt. et Appl.*, 2 (1897), No. 5, p. 291; *abs. in Chem. Ztg.*, 21 (1897), No. 77, *Repert.*, p. 211).—The errors incident to the citrate method are pointed out and it is recommended to dissolve the phosphate in boiling nitric acid and precipitate in very dilute solution with ammonium molybdate. The method then proceeds as usual except that the precipitate of ammonium-magnesium phosphate and the filter are ignited separately to prevent reduction and loss of phosphoric acid.

**The quick determination of phosphorus, H. WADOWISZEWSKI** (*Stahl u. Eisen*, 17 (1897), p. 814; *abs. in Chem. Ztg.*, 21 (1897), No. 87, *Repert.*, p. 248).—A method applicable to iron and steel analysis. Dissolve 2 gm. in 30 cc. nitric acid (1.2 sp. gr.), dilute to 50 cc., and filter. Evaporate filtrate to original volume, oxidize with potassium permanganate, add hydrochloric acid to dissolve the manganese dioxid, cool, and neutralize with ammonia. Warm to 60° C., add molybdic solution, shake for 5 minutes, and let stand  $\frac{1}{4}$  hour. Filter, wash the precipitate with 10 per cent ammonium nitrate solution, and dissolve in ammonia. Neutralize with hydrochloric acid, add magnesia mixture and excess of ammonia, allow to stand  $\frac{1}{4}$  hour in ice or snow, shake 5 minutes, and filter.

**Determination of phosphoric acid in natural phosphates, E. HÉNIN** (*Ann. Chim. Analyt. et Appl.*, 2 (1897), p. 285; *abs. in Chem. Ztg.*, 21 (1897), No. 77, *Repert.*, p. 211).—A form of Villier's method is used.

**Estimation of alumina in phosphates, H. LASNE and VON GRUEBER** (*Ztschr. Angew. Chem.*, 1897, pp. 276-278; *abs. in Jour. Chem. Soc. [London]*, 72 (1897), No. 420, II, p. 518).—Lasne claims priority for the use of sodium hydroxid in the separation of aluminum phosphate from iron and other phosphates. Von Grueber replies that he was not acquainted with Lasne's investigations when he published his method.

**Estimation of sodium in the presence of potassium, F. F. BELLSTEIN and O. VON BLAESE** (*Bul. Acad. Impér. Sci. St. Petersbourg*, 33, p. 209; *abs. in Ztschr. Analyt. Chem.*, 36 (1897), p. 513; *Jour. Chem. Soc. [London]*, 72 (1897), No. 420, II, p. 518).—"To the

solution of the chlorids or nitrates, a solution of potassium antimonate is added. The supernatant liquid is decanted after 24 hours and the precipitate washed, first with a 0.7 per cent solution of potassium acetate, and then with 50 per cent alcohol. After ignition, it is weighed as  $\text{NaSbO}_3$ . For each 100 cc. of the decanted liquid (which must not contain potassium carbonate), 0.0233 gm. must be added to correct for solubility."

**Determination of boric acid in meat products**, C. FRESSENIUS and G. POPP (*Ztsch. Öffentl. Chem.*, 3, p. 188; *abs. in Analyst*, 22 (1897), Nov., p. 282).

**On the titration of sulphuric acid solutions**, F. MARBOUTIN and A. PÉCOUL (*Bul. Soc. Chim. Paris*, 3. ser., 17 (1897), No. 18-19, pp. 880, 881).

**A new receiver for the steam distillation of oils**, A. JUNGHAIN (*Chem. Ztg.*, 21 (1897), No. 68, p. 669, fig. 1).—A covered beaker is tubulated on the side near the top for the reception of the short arm of a siphon, which reaches to the bottom of the receiver and which is open at the bend. As the products of distillation accumulate, the oil on top and the water at bottom, the level of the liquid reaches that of the bend in the tube, and any further addition of liquid causes an equal amount of water to flow out through the tube. When the distillation is completed, all the water may be siphoned out by closing the aperture in the siphon with the thumb and filling the tube with water by tilting the beaker. When all the water is out and the oil is about to escape, the thumb is removed and the siphoning ceases.—J. T. ANDERSON.

**A self-regulating gas generator**, W. W. ANDREWS (*Chem. Ztg.*, 21 (1897), No. 68, pp. 666, 667, figs. 2).—The apparatus consists of 2 parts, an acid flask and a generator proper. The first is in the form of a wash bottle, the longer tube reaching down a little way into the acid and being connected at the other end, by means of a rubber tube, with the generator, so as to form a siphon. The generator is a Fresenius calcium chlorid tower, the material to be decomposed resting on a perforated floor just above the bottom. A tube at the top with a stopcock regulates the flow of gas. To put the apparatus in operation, open the cock and blow into the acid flask to fill the siphon. When the cock is closed the pressure drives the acid back into its flask, and by reason of its greater density it settles to the bottom without mixing with the other acid. To facilitate this a mantle tube surrounds the short arm of the siphon and reaches to the bottom of the flask. Openings at the top of this mantle allow fresh acid to enter it, so that fresh, unused acid is siphoned into the generator each time.—J. T. ANDERSON.

**A new form of hydrogen generator**, E. W. MAGRUDER (*Amer. Chem. Jour.*, 19 (1897), No. 9, pp. 810-812).

**A new support on the Bunsen burner**, E. STEIGER (*Chem. Ztg.*, 21 (1897), No. 68, p. 668, figs. 3).—The ordinary sheet-iron cone is replaced by a cylinder which is securely fastened in place by a screw, and on this cylinder the vessel to be heated is placed. Either a wire triangle, a wire gauze, or an asbestos plate may be used with it.—J. T. ANDERSON.

**A new form of burette**, C. SANDER-PRAYON-LEZ-TROOZ (*Chem. Ztg.*, 21 (1897), No. 74, p. 739, fig. 1).

## BOTANY.

**An important function of leaves**, U. SUZUKI (*Imp. Univ. Col. Agr. [Tokyo] Bul.*, vol. 3, No. 3, pp. 241-252).—The author examined leaves of quite a number of species of plants to determine: (1) The decomposition of proteids and transportation of the decomposed products to other

parts of the plant; (2) is the gradual oxidation of the amido acids observable? and (3) are the amido compounds, such as leucin and asparagin, better sources of nitrogen for the protein in fruits and roots than nitrates?

The experiments were conducted during September and October, the leaves being collected at 6 a. m. and 6 p. m., after having been exposed to approximately 12 hours of light or darkness. The total nitrogen, albuminoid nitrogen, asparagin nitrogen, and starch were determined.

The conclusions of the author seem to indicate that reserve proteids in the leaves are decomposed into amido compounds during the night and they are quickly transported to other parts of the plant. This important function of the leaves assists in facilitating the formation of proteids in all parts of the plant. The amido compounds are considered better sources for protein formation than the nitrates, especially in those organs of the plant which are poor in sugar and have little respiratory energy. This function is especially important in plants of rapid growth, as some of the legumes or in those developing large storage organs, as potatoes, turnips, melons, etc.

The amido compounds formed are either asparagin, which can be formed synthetically from ammonium salts as well as the nitrates, or they are decomposition products of proteids formed in the assimilation of nitrates.

**On the behavior of active albumin as a reserve material during winter and spring**, U. SUZUKI (*Imp. Univ. Col. Agr. [Tokyo] Bul., vol. 3, No. 3, pp. 253-258*).—The author examined the buds and bark of 48 species of trees and shrubs and found active albumin as a reserve material in 25 of them. It was frequently found more abundant in the bark than in the buds. In this respect it behaves like other reserve materials.

The details of the experiments are fully described.

**On the physiological action of neutral sodium sulphite on phanerogams**, K. NEGAMI (*Imp. Univ. Col. Agr. [Tokyo] Bul., vol. 3, No. 3, pp. 259-264*).—The effect of neutral sodium sulphite on various phanerogams was investigated. Solutions containing 1 per cent of neutral sodium sulphate were freshly prepared and changed every 2 days, since it oxidizes into sulphate very rapidly. Whole plants, branches, leaves, and seeds were experimented with and the poisonous effect of sodium sulphite upon developed plants was established. It seemed to have no noxious effect on the germination of radish and barley seeds, although the germination of soy beans was retarded to some extent.

**The poisonous action of ammonium salts on plants**, S. TAKA-BAYASHI (*Imp. Univ. Col. Agr. [Tokyo] Bul., vol. 3, No. 3, pp. 265-274*).—Experiments were conducted to test the effect of ammonium carbonate, sulphate, and chlorid on plant growth, comparing them with sodium carbonate and sulphate. A dozen or more kinds of plants were grown in culture solutions containing varying amounts of the chemicals. The

experiments with barley, wheat, and onions are reported upon in considerable detail.

The method of experimentation was to keep half the objects in darkness until most of the reserve material was used up, the other portion being kept in the light for the same time in a solution containing cane sugar. When the reserve material was nearly exhausted both lots of plants were placed in the solutions containing the ammonium compounds and kept in darkness.

It was soon found that the sugar solutions checked the injurious action of the weaker ammonium solutions, but had little if any influence when the stronger (0.5 per cent) solutions were used. This action is explained by the greater osmotic action of the ammonium solutions. When the cells are already filled with sugar or glycerol the entrance of the injurious element is impeded.

The general conclusion is that, "From all the observations described, it follows that ammonium salts have a noxious action upon phanerogamous plants if there is not a sufficient quantity of sugar present in the plant. The sugar may convert the noxious ammonia into asparagin, and as a consequence the noxious action is not noticed in well-nourished plants."

The principal phenomena of the poisonous effect of ammonium carbonate were a loss of turgidity and softening of the roots, loss of turgidity and appearance of brown spots on leaves, and change of color in the culture medium due to discoloration from the dead cells of the plant.

**Notes on the grasses and forage plants of Iowa, Nebraska, and Colorado,** L. H. PAMMEL (*U. S. Dept. Agr., Division of Agrostology Bul. 9, pp. 47, figs. 12*).—The report given includes general observations of the author on the physical conditions and other important questions relative to forage production in the States named; an enumeration of the more important grasses and forage plants occurring in the States, with economic notes, and a classified list of the grasses collected by the author during the seasons of 1895 and 1896 in Iowa, Nebraska, and Colorado.

**Notes on the plants used by the Klamath Indians of Oregon,** F. V. COVILLE (*U. S. Dept. Agr., Division of Botany, Contributions from the U. S. National Herbarium, vol. 5, No. 2, pp. 87-108*).—The author gives notes on the economic uses of plants by the Klamath Indians of Oregon, based upon his observations while engaged in a botanical survey of the plains of southeastern Oregon in the summer of 1896.

**Studies of Mexican and Central American plants,** J. N. ROSE (*U. S. Dept. Agr., Division of Botany, Contributions from the U. S. National Herbarium, vol. 5, No. 3, pp. 109-144, pls. 16, figs. 6*).—Notes are given on a number of species of the orders Celastraceæ, Rutaceæ, Burseraceæ, and Cucurbitaceæ, and on miscellaneous genera and species; also synopses of the species of *Heliocarpus*, *Wimmeria*, the American species *Hermmannia*, and *Drymaria nodosa* and its allies, and descriptions of miscellaneous new species.

**The vegetation of the Yellowstone Hot Springs**, J. W. HARSIBERGER (*Amer. Jour. Pharm.*, 69 (1897), No. 12, pp. 625-634).—Among other forms of plant life found growing in these hot springs the author mentions *Leptothrix laminosa* growing at 135 to 185° F., *Phormidium* at 165°, and *Beggiatoa* at 150 to 165°.

**A revision of the species of *Plantago* occurring in the United States**, A. M. CUNNINGHAM (*Proc. Indiana Acad. Sci.*, 1896, pp. 190-207, pl. 1).—Two new species, *P. rubra*, separated from *P. virginica*, and *P. minima*, separated from *P. patagonica gnaphalioides*, are described.

**Botany of pampas grass and its allies**, O. STAFF (*Gard. Chron.*, 3. ser., 22 (1897), Nos. 569, p. 358; 570, p. 378).—Notes are given of *Gynerium argenteum*, *G. saccharoides*, and their allies.

**Investigation of important grasses at Bergshamra**, C. E. BERGSTRAND (*Biet [Helsingfors]*, 18 (1897), No. 2, pp. 46-56).—The yield, composition, and general value of the following grasses are considered: *Dactylis glomerata*, *Festuca pratensis*, *Arena elatior*, and *Phleum pratense*.

**Cytological studies of fungi**, A. N. BERLESE (*Riv. Patol. Veg.*, 6 (1897), No. 1-5, pp. 66-75).—Cytological studies are given of *Oidium monilioides* and *O. erysiphoides*.

The alkaloid of the black lupine, K. GERHARD (*Arch. Pharm.*, 235 (1897), No. 5).

Concerning the alkaloid of the perennial lupines, K. GERHARD (*Arch. Pharm.*, 235 (1897), No. 5).

On the effect of alkaloids on plants in the light and darkness, G. SCHWARTZ (*Inaug. Diss., Erlangen*, 1897, pp. 49).

On the influence of light on growth, K. STAMEROFF (*Flora*, 83 (1897), pp. 135-150; *abs. in Bot. Centbl.*, 72 (1897), No. 5, p. 179).—The author found that the vegetative hyphæ of *Mucor* and *Saprolegnia* grew equally well in light and darkness, while the growth of the reproductive hyphæ of *Mucor* was checked in the light. The rhizoids of *Marchantia* grew better in light than in darkness. The pollen tubes of *Colutea arborescens* and *Robinia pseudacacia* did not grow in the light. The pollen tubes did not make equal growth and it was largely controlled by the amount of sugar in the medium.

Concerning the specific heat of plants, H. SIMMER (*Allg. Bot. Ztschr. Syst. Flor. Pflanzengeog., etc.*, 3 (1897) No. 10, pp. 160-163).

## FERMENTATION—BACTERIOLOGY.

On the origin of sake yeast, K. YABE (*Imp. Univ. Col. Agr. [Tokyo] Bul.*, vol. 3, No. 3, pp. 221-224).—The author has investigated the origin of sake yeast (*Saccharomyces sake*) which develops so rapidly in certain stages of sake brewing. The hypothesis that it is derived from *Aspergillus oryzae* is not accepted, pure cultures of that fungus proving incapable of forming the yeast cells. Examinations made of air in the botanic garden, while showing numerous fungi, did not include any sake yeast. Yeast cells were found in considerable number in the cellars where the fermenting rice is kept. A sterile plate 9 cm. in diameter exposed for 30 minutes to the air of the cellar contained, after 76 days, 207 colonies of *Penicillium*, 76 of *Aspergillus*, and 36 of yeast. The source whence the yeast came into the cellar is stated to be the rice straw, mats of which are extensively used in the first stage of sake manufacture. Examinations made of rice straw from mattings in the cellar, from fresh straw from the fields, and from soil from rice fields all showed the presence of the sake yeast.

The sake yeast cells are globular or slightly ellipsoid in form, 5 to 9 $\mu$  in diameter, usually 7 $\mu$ . In budding the cells soon separate, seldom or never forming the long chains seen in some yeasts.

The yeast forms on gypsum blocks, but not in the fermenting liquid, 1 to 3 ascospores, a previous good nutrition rather rich in protein being necessary to ascospore formation. The author has not proved that the ascospores are capable of producing the yeast cells. No trace of anything resembling a mycelium, as claimed by Korschelt,<sup>1</sup> was observed.

Sake yeast is said to be capable of continuing fermentation in the

<sup>1</sup>Mit. Gesell. Ostasien, Tokyo, 1878.

presence of 12 per cent alcohol and feebly at 16 per cent. Small quantities of some of the higher alcohols check its growth. Cane sugar solutions containing meat extract are fermented by it even when containing as much as 45 per cent cane sugar. Salt in small quantity does not check it, while 22 per cent stops it entirely. Solutions containing 10 per cent cane sugar and 4 per cent tartaric acid do not admit the growth of the yeast.

Several other agents of fermentation derived from rice straw are mentioned, among them the organism depended upon for ripening the vegetable cheese, natto, the Javanese arrac, a diastase-yielding fungus and *Saccharomyces vordermanni*.

**On the behavior of yeast at a high temperature,** T. NAKAMURA (*Imp. Univ. Col. Agr. [Tokyo] Bul., vol. 3, No. 3, pp. 227-232*).—The author experimented with pure cultures of yeast obtained from a single colony. A description of the method of treatment is given. It was found that exposing the yeast in a water bath for  $1\frac{1}{2}$  hours at  $46^{\circ}$  C. or 1 hour at  $48^{\circ}$  C. did not destroy its fermenting power. At a temperature of  $52^{\circ}$  C. the power to produce fermentation was destroyed if continued for more than 20 minutes.

It was found that the thermal point at which the fermenting power was destroyed was  $50^{\circ}$  C. for 30 minutes' exposure. With between 25 and 30 minutes' exposure at the above temperature, the yeast still gave feeble fermentation for a short time, after which it ceased, although but a very small portion of the sugar had been used up. It is inferred that exposure for 25 minutes to a temperature of  $50^{\circ}$  C. forms the limit, not only of fermenting power, but life functions as well.

The effect on the resistant power of the organism of adding various compounds to the culture medium was tested and meat extract, sodium chlorid, and sodium nitrate served to increase the resisting power of the yeast.

In an appended note by Dr. O. Loew, the phenomenon of suspended fermenting power in living cells is explained by the statement of Buchner<sup>1</sup> "That the fermentative power is connected with a soluble proteid that can be separated by expressing the yeast under a pressure of 400 to 500 atmospheres." This substance, called zymose, coagulates easily, and after a few days loses its active properties. It is similarly affected by heating to  $50^{\circ}$  C. or more.

**Note on a grape wine fermented by sake yeast,** K. NEGAMI (*Imp. Univ. Col. Agr. [Tokyo] Bul., vol. 3, No. 3, pp. 225, 226*).—Two liters of freshly prepared grape juice were sterilized by boiling and after cooling inoculated with a pure culture of sake yeast. After 2 months fermentation at from 5 to  $20^{\circ}$  C., the clear filtered liquid gave extract 1.78 per cent, acidity 0.572 per cent, alcohol 10.30 per cent. The taste was equal to that of the average white wine, but the bouquet was inferior. The yeast can not be used to replace the usual ferments of wine making.

<sup>1</sup> Ber. Deut. Chem. Gesell., 30 (1896), p. 117.

**Bromalbumin and its behavior toward microbes**, O. LOEW and S. TAKABAYASHI (*Imp. Univ. Col. Agr. [Tokyo] Bul.*, vol. 3, No. 3, pp. 237-240).—On account of the recommendation of some medical practitioners of bromalbumin to secure immunity from certain bacterial diseases, the authors were led to investigate its action. Fresh material, which is an organic compound of bromin, was prepared and tested upon the bacteria of putrefaction and the bacillus of anthrax. It was found in the absence of air to be somewhat unfavorable to the development of the bacteria. When peptones were present, it did not prevent growth. Preliminary experiments with mice showed that subcutaneous injections of bromalbumin did not secure immunity from anthrax and erysipelas.

**Two new kinds of red yeast**, K. YABE (*Imp. Univ. Col. Agr. [Tokyo] Bul.*, vol. 3, No. 3, pp. 233-236).—The author describes 2 new species of red yeasts, *Saccharomyces japonicus* and *S. keiskeana*. They were found on rice straw and soil of rice fields, and are closely related to *S. rosaceus*.

**Notes on fermentation**, I. J. HAGE (*Arch. Gen. Med.*, 1897, pp. 157-165).

**A text-book on bacteriology**, E. M. CROOKSHANK (*London: H. G. Lewis*, 1896, pp. 715, pls. 22, figs. 273).—This important work discusses the etiology and prevention of infectious diseases, and gives also an account of yeast, hæmatozoa, psorosperms

or coccidia, bacteriological parasites, and reagents. In a supplementary appendix are given extracts from the report of the Royal Vaccination Commission for 1896. The distinctive features of various pathogenic bacteria and their cultures are brought out in colors. The contagious diseases of animals are treated, and the most stringent measures insisted upon in combating them. The carcasses of animals that have died of anthrax, for instance, should, one is told, be buried deep and with a liberal use of lime in and around the hole. The spot where the animal died should be sprinkled with lime and fenced off for some time. The carcass should by no means be allowed to get into a stream.

In discussing tuberculosis, the congenital transmission of the disease is insisted on in a way that would lead one to infer that such transmission is more common than American and Russian experiments indicate. But no experimental evidence is cited.

**A simple method of preparing nutrient agar**, H. B. SHEFFIELD (*Merck's Rpt.*, 6 (1897), No. 24, p. 762).

**Paraffin sectioning technique**, F. BLOCHMANN (*Ztschr. Wiss. Micros.*, 14 (1897), No. 2, pp. 189-195, fig. 1).

**A process for rapid microscopical investigation of bacteria in cover-glass and glass-slide preparations**, D. KISCHENSKY (*Centbl. Bakt. u. Par.*, 1. Abt., 21 (1897), No. 22-23, pp. 876, 877).—A drop of pure culture is placed in a drop of weak carbol-fuchsin (10 drops in 10 cc. water) on a cover glass and fixed, stained, and dried at the same time in the flame of a lamp. All 3 processes thus combined require only a few seconds. When dealing with bacteria in feces and urinal sediment, it will be found better, it is said, if with the carbol-fuchsin an alcoholic solution of methylene blue be mixed.

**On a special procedure for staining bacteria in cover-glass preparations and in sections**, W. SEMENOWICZ and E. MARZINOWSKY (*Centbl. Bakt. u. Par.*, 1. Abt., 21 (1897), No. 22-23, pp. 874-876).—In cover-glass preparations the cover glass is left for 2 minutes in carbol-fuchsin, consisting of the ordinary concentrated solution diluted to one-half with water. It is then washed in water and afterwards stained for 3 to 4 minutes with Loeffler's methylene blue. Sections are allowed to remain in the carbol-fuchsin 4 to 5 minutes, and for the same length of time in methylene blue. The preparations are then in both cases mounted in Canada balsam by the usual methods. The bacteria stand out strongly in the preparations as blue objects on a red or rosy background. The essential usefulness of the method is thought to lie in the fact that the methylene blue causes a change in the carbol-fuchsin, appearing in the nuclei and bacteria sooner than in the cytoplasm of the cells or in the connective tissues. As methylene blue does not act so alone, it appears that the carbol-fuchsin has the action of a mordant. But if the carbol-fuchsin be replaced by 5 per cent carbolic acid, and specimens treated for 5 minutes therein, the bacteria and nuclei become more deeply stained than by methylene blue alone. But a good staining may be obtained with carbol-fuchsin. Hence the author thinks that it is the fuchsin that acts as a mordant.

**Chemical disinfection**, A. GAWALOWSKI (*Ztschr. Nahr. Untersuch. u. Hyg.*, 11 (1897), No. 14, p. 233).—A table is given showing the relative value of a number of substances as deodorants, disinfectants, and antiseptics.

**A method of staining flagella**, D. McCRRORIE (*Internat. Jour. Micros. and Nat. Sci.*, 3. ser., 7 (1897), No. 35, pp. 212, 213).—The objects are stained in a mixture composed of concentrated alcoholic solution of "night blue" 10 cc., 10 per cent solution

of alum 10 cc., and 10 per cent solution of tannic acid 10 cc. One-tenth to two-tenths gram of gallic acid may be added as a mordant, but good results may be obtained without it.

### ZOOLOGY.

**Animals useful and injurious to horticulture**, A. LARBALÉTRIER (*Les animaux utiles et nuisibles à l'horticulture (insects execeptes)*). Paris: Octave Doin, 1897, pp. 153, figs. 29).—This excepts the groups of insects and treats of the mammals, birds, batrachia, reptiles, arthropoda other than insects, worms, and mollusks, that may be considered either injurious or useful to horticulture. The habits of the animals, their characteristics, the character of the damages done by them, their general habits, and means for protection against them are briefly brought out.

Among myriapods Geophilidae are described as injurious to the tubers of certain plants such as the potato. Kirby is quoted as authority for the statement that they live in galleries in the roots of these plants. The species mentioned is *Geophilus longicornis*, and along with it as a companion is noted *Polydesmus complanatus*. *Julus terrestris* is noted as injurious, and also *Glomeris marginata*, Savigny's cryptops, and *Lithobius forficatus*. The very beneficial earthworm (*Lumbricus terrestris*), where it is very numerous, is considered something of a pest.

**Laboratory directions in general biology**, H. RANDOLPH (*New York: Henry Holt & Co., 1897, pp. 162*).—This is a student's handbook of directions for a full year's course in general biology, in which 6 hours per week of work is expected. As an aid to the teacher, the proportionate amount of work to be devoted to each subject is tabularly set forth. The laboratory directions, which are brief, begin with the fern, which is followed by the earthworm. To each of these subjects 10 hours are devoted. Then follow the amœba, white blood corpuscle, hæmatococcus, paramecium, vorticella, penicillium, lichens, mushrooms, bacteria, spirogyra, hydra, muscle, lobster, etc. The work finally ends with directions for a brief study of the embryology of the chick.

### METEOROLOGY.

**United States daily atmospheric survey**, W. L. MOORE (*U. S. Dept. Agr., Weather Bureau Doc. 138, pp. 6*).—This is a reprint of a paper read before the geographical section of the British Association for the Advancement of Science, Toronto, August 23, 1897.<sup>1</sup>

“The vast region now brought under the dominion of twice-daily synchronous observations embraces an area extending 2,000 miles north and south, 3,000 miles east and west, and so fortunately located in the interest of the meteorologist as to cut an important arc from the circumpolar thoroughfare of storms of the Northern Hemisphere. The extreme points of observation are Edmondton, in the Canadian Province of Alberta, on the northwest; St. Johns, on the northeast; Key West, on the southeast, and San Diego on the southwest; and arrangements are now complete for a cooperation with Mexico similar to that in operation with Canada, which will in a few months extend the area of observation southward over Mexico and Yucatan.”

The opinion is expressed that by means of this system of observations the highest degree of accuracy in making forecasts possible to be attained with surface readings has been reached.

The Weather Bureau has undertaken “to systematically attack the problem of upper-air exploration, with the hope ultimately of being

<sup>1</sup> Nat. Geog. Mag., 8 (1897), pp. 299-303.

able to construct a daily synoptic weather chart from simultaneous readings taken in free air at an altitude of not less than one mile above the earth." The success in this line has been such that it is probable that in a short time there will be "not less than 20 stations placed between the Rocky Mountains and the Atlantic Ocean, taking daily readings at an elevation of 1 mile or more."

"We shall then construct a chart from the high-level readings obtained at these 20 stations and study the same in connection with the surface chart made at the same moment. Being thus able to map out not only the vertical gradients of temperature, humidity, pressure, and wind velocity, but the horizontal distribution of these forces on two levels, it is hoped to better understand the development of storms and cold waves and eventually improve the forecasts of their future course, extent, and rate of movement."

**Report of the Chief of the Weather Bureau for 1897, W. L. MOORE** (*U. S. Dept. Agr., Weather Bureau Doc. 139, pp. 28*).—A summary report of the operations of the Weather Bureau during the fiscal year ending June 30, 1897, covering the following topics: Comparison of cost and efficiency of the Weather Service, 1883-'84 and 1896-'97; appropriations for 1898; forecasts (destructive storms of the year, flood warnings, and flood in the lower Mississippi); hydrography (description of the river system); cold-wave and frost warnings; distribution of forecasts and warnings; distribution of weather statistics by maps; climatic work, cotton, corn, and wheat region services; publications; original investigations and reports; climatology, studies of sunstroke and weather conditions; rainfall of the United States; some climatic features of the arid region; storms, storm tracks, and weather forecasting; aerial work; improvements in kite construction; the object of kite flying; and cloud work.

**Instructions for use of aneroid barographs on the Great Lakes, W. L. MOORE** (*U. S. Dept. Agr., Weather Bureau Doc. 133, pp. 7, fig. 1*).—The aneroid barograph is described and directions are given for its use.

**Weather record for 1896 at Newport, Arkansas** (*Arkansas Sta. Bul. 46, p. 100*).—A tabular record is given of maximum and minimum temperatures and rainfall for each day of the 5 months, April–August, 1896.

## WATER—SOILS.

**Soil moisture during the crop season of 1896, M. WHITNEY and R. S. HOSMER** (*U. S. Dept. Agr., Division of Soils Bul. 9, pp. 23, figs. 12*).—This is a continuation of work begun in 1895.<sup>1</sup> "In a number of cases the records were continued in the same places as in the previous year, but in order to extend the preliminary investigations over a wide range of soil conditions, some of the observations were discontinued and other areas were taken up." The method of determining moisture was the same as that used in 1895.<sup>2</sup> The results, however, are reported

<sup>1</sup> U. S. Dept. Agr., Division of Soils Buls. 1, 2, and 3 (E. S. R., 7, pp. 483, 847).

<sup>2</sup> U. S. Dept. Agr., Division of Soils Bul. 4 (E. S. R., 8, p. 481).

on the basis of dry weight of soil, a table being given by which percentages calculated on the fresh weight may be converted into those calculated on the dry weight.

Tables and diagrams show the daily variation in the moisture content of the soil during April to September in early truck land at Mardela Springs, Maryland; blue grass (Trenton limestone) land at Lexington, Kentucky; cotton land (Red Hill formation) at St. Matthews, South Carolina; sandy cretaceous cotton land at Union Springs, Alabama; sandy cretaceous cotton land at Fort Deposit, Alabama; black cretaceous prairie at Macon, Mississippi; black clay of the Mississippi bottom at Greenville, Mississippi; black waxy soil at Paris, Texas, and prairie land at Colby, Kansas.

“Curves illustrate in a graphic way the conditions in several soils during a period of quite marked drought, during which crops suffered, in the season of 1896.” These and other data in the case of some of the soils which have been studied for some time under different weather conditions have been used as a basis for approximately establishing lines of excessive moisture and of drought in the soils.

**Researches on the drainage waters of bare and cultivated soils**, P. P. DEHÉRAIN (*Ann. Agron.*, 23 (1897), No. 6, pp. 241-267).—This is a summary of observations on the vegetation boxes at Grignon during 5 years.<sup>1</sup> The results clearly demonstrate that the quantity of nitrates removed by the drainage water from bare soils is very much greater than that removed from soils covered with a crop, and this discrepancy is not in every case entirely accounted for by the amount of nitrates utilized by the plant.

From the data obtained in experiments with wheat, it is estimated that the amount of nitric nitrogen utilized by the crop and removed in the drainage water was only 94 kg., while the amount of nitric nitrogen found in the drainage water from a check plat of bare soil was 200 kg. The wide discrepancy in this case may be partially accounted for by the fact that during a part of the growing season of the wheat the moisture was not sufficient for the needs of the crop and for active nitrification in the soil. In experiments with corn, during the growing season in which the rainfall was abundant, the amount of nitric nitrogen utilized by the crop and found in the drainage water was 197 kg., as compared with 200 kg. found in the drainage water of bare soils.

These results show in general that the soils experimented on are capable, with a sufficient supply of moisture, of furnishing all the nitrates required by the largest crops, and indicate that if provision were made for a sufficient supply of irrigation water at all periods of the growing season, nitrification would be so promoted that much smaller applications of nitrogenous fertilizers would be required.

<sup>1</sup> For abstracts of previous work in this line see E. S. R., 6, p. 977.

**Production of humus from manures**, H. SNYDER (*Minnesota Sta. Bul. 53, pp. 12-35, fig. 1*).—This is a continuation of previous work.<sup>1</sup> In order to study the variation in composition of humus and humates of different origin these products were prepared from known materials in the following way: 200 gm. of sugar was mixed with 3,000 gm. of soil containing a small known amount of organic matter, placed in a tight box, and allowed to undergo decomposition out of doors for one year. Humus was produced in the same way from cow manure, green clover, meat scraps, wheat flour, sawdust, oat straw, and asparagin. The humus produced was extracted from the soil, after treatment with dilute hydrochloric acid and distilled water, with a 3 per cent solution of potassium hydroxid. The precipitates obtained by neutralizing with hydrochloric acid were washed, dried, and analyzed. The results are given in the following table:

*Composition of humus produced by different organic substances.*

	Cow manure.	Green clover.	Meat scraps.	Wheat flour.	Oat straw.	Sawdust.	Sugar.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Carbon.....	41.95	54.22	48.77	51.02	54.30	49.28	57.84
Hydrogen.....	6.26	3.40	4.30	3.82	2.48	3.33	3.04
Nitrogen.....	6.16	8.24	10.96	5.02	2.50	.32	.03
Oxygen.....	45.63	34.14	35.97	40.14	40.72	47.07	31.0
Total.....	100.00	100.00	100.00	100.00	100.00	100.00	100.00

This table shows wide variations in the composition of humus produced by the decomposition of different materials. None of the materials analyzed agreed in composition with the formulas in Mulder's classification, and "it is evident that any formulas applied to the compounds as a whole would, to say the least, fail to express the composition of humus."

"It would seem best, in the present state of our knowledge of the humus compounds, to make the division on the basis of the nitrogen content; that is, divide the humus compounds into classes, as follows:

"(1) Non-nitrogenous group, as sugar humus. (2) Humus containing 1 to 2 per cent nitrogen, as sawdust humus. (3) Humus containing 2 to 4 per cent nitrogen, as oat-straw humus. (4) Humus containing 4 to 8 per cent nitrogen, as flour and cow manure humus. (5) Humus containing over 8 or 9 per cent nitrogen.

"Such a division would give an approximate idea as to the nature of the material from which the humus has been produced, as well as an approximate idea of its agricultural value. . . .

"The humate compounds do not form well-defined crystallized bodies, and it is almost impossible to obtain any one of these compounds in a pure state, to study the structural composition."

In order to decide whether the mineral constituents found in humus are furnished entirely by the mineral matter in the humus-forming material or are partly derived from the soil by the chemical action of the humus, the phosphoric acid and potash in the soil and humus-forming materials at the beginning of the experiment and in the humus

<sup>1</sup> Minnesota Sta. Buls. 30 and 41 (E. S. R., 5, p. 857; 7, p. 476).

obtained were determined. The results are summarized in the following table:

*Phosphoric acid and potash in humates produced by different materials.*

	Phosphoric acid.		Potash.	
	In original materials.	In final product.	In original materials.	In final product.
	Grams.	Grams.	Grams.	Grams.
Cow-manure humus.....	1.17	1.62	1.06	1.27
Green-clover humus.....	3.21	3.74	5.26	4.93
Meat-scrap humus.....	1.07	1.18	.25	.36
Sawdust humus.....	.85	.78	.67	.70
Flour humus.....	.60	.71	.32	.48
Oat-straw humus.....	1.02	1.03	2.42	2.41

This table shows that there is a wide difference in the power which various humus-forming materials possess of forming humates with the mineral matter of the soil. The nitrogenous materials appear to be most active in this respect. There is also a great difference in the readiness with which soils combine with the humus.

Analyses of the humus of new and old soils are reported which show that "in the long-cultivated soil the humus contains more carbon and holds less nitrogen and mineral matter in chemical combination than in the new soil."

The influence of different methods of farming on the humus content of the soil, the effect of forest fires, and the humus requirements of soils are briefly discussed; and the average composition of the mineral matter of the humus of a large number of samples of soils is reported.

**Production of ammonia at the expense of organic matter and humus,** E. BRÉAL (*Ann. Agron.*, 23 (1897), No. 8, pp. 356-369).—A series of determinations of ammonia in plants and soils treated in different ways are reported, which led to the following conclusions:

(1) Ammonia is produced in soils and in plants in which growth has been checked. A plant in vigorous growth does not produce ammonia.

(2) Ammonia appears in the tissues of plants in a few hours if they are deprived of air or treated with anaesthetics, such as ether or chloroform.

(3) Air-dry vegetable matter with a limited supply of air evolves ammonia.

(4) In the presence of water not only plant remains but such stable nitrogenous substances as feathers, wool, horn, and leather give off ammonia.

(5) The humus of the soil also becomes a source of ammonia when it is brought in contact with leaves in which fermentation has been set up by a vegetable infusion.

(6) A fragment of leaf not only produces ammonia in the soil, but it is possible to measure the amount produced if the soil has previously been sterilized.

(7) Manure not only evolves ammonia itself, but also causes the production of ammonia by the humus of the soil.

(8) Plants absorb ammonia supplied to their roots. This is shown by

the accumulation of ammonia in the roots when the upper part of the plant is removed.

(9) When roots detached from the stems are brought in contact with the nitrogenous matter of the soil they form ammonia at the expense of this matter.

(10) A plant rooted in the soil has been found to produce more ammonia at the expense of the soil than it was able to utilize.

**Soil improvement**, R. L. BENNETT, G. B. IRBY, and C. L. NEWMAN (*Arkansas Sta. Bul. 46, pp. 79-99, fig. 1*).—The results of experiments during the past 6 years on the improvement of worn cotton soil and the best form and manner in which to apply fertilizers are summarized and the results of experiments during 1896 along this line at the northeast substation at Newport and the southern substation at Camden are reported.

Past experiments have indicated that “(1) Worn cotton soils need nitrogen, vegetable matter, better tillage, and better protection. (2) The cheapest, most durable, and available form to apply nitrogen is vegetable nitrogen in the form of cowpeas, cotton seed, and cotton-seed meal. (3) One crop of cowpeas turned in the soil will furnish more nitrogen than is necessary for one crop of corn or cotton. (4) Most Arkansas clayey soils do not need an addition of potash and phosphoric acid for staple crops if the soil’s supply of those foods is made available and increased and the soil water increased by thorough and continuous tillage and by rotation with cowpeas. The exception to this is the deficiency of available potash and phosphoric acid in the sandy pine soils of South Arkansas. On that soil it may be profitable to use potash and phosphoric acid to a limited extent, but only after first testing to ascertain that extent. (5) Kainit and acid phosphate, 13 per cent and 14 per cent available, are the best forms in which to purchase potash and phosphoric acid.”

The experiments at Newport were undertaken to ascertain the value of commercial fertilizers, cotton-seed meal, and barnyard manure for cotton and for corn and the effect of rotation on these crops. Three experiments were made with the same kinds and amounts of fertilizers. In experiment No. 1 the crop was grown after 2 crops of cotton, in experiment No. 2 after 2 crops of turned-under cowpeas, and in experiment No. 3 on worn cotton soil after a crop of peas and a crop of cotton. The following table shows the results:

*Results of fertilizer experiments at Newport, Arkansas.*

Fertilizers applied per acre.	Yield per acre.		
	Experi- ment 1, seed cotton.	Experi- ment 2, seed cotton.	Experi- ment 3, corn.
	Pounds.	Pounds.	Bushels.
No fertilizer .....	932	1,304	20
Nitrate of soda, 200 lbs., 16 per cent nitrogen .....	1,145	1,265	32
Muriate of potash, 300 lbs., 49 per cent potash .....	950	1,329	13
Acid phosphate, 300 lbs., 14 per cent phosphoric acid .....	960	1,381	19
Gypsum, 500 lbs .....	852	1,315	14
Cotton-seed meal, 400 lbs., 6 per cent nitrogen .....	1,080	1,213	29
Kainit, 400 pounds, 13 per cent potash .....	840	1,134	15
Barnyard manure, 10 loads .....	1,122	1,207	26

Plats manured with nitrogenous fertilizers gave the best results, but in experiment No. 2 all the fertilizers had very little, if any, effect.

No advantage was gained by applying potash, phosphoric acid, and lime to a crop of peas to be used by them before turning under for cotton and corn instead of applying these fertilizers directly to the corn or cotton crop.

Manure experiments with wheat on sandy soils showed that peas planted July 31 and turned under green October 10 were more effective than commercial fertilizers and even horse manure.

Cowpea vines turned under and cotton meal were more effective for grass, clover, and potatoes on worn cotton soils than commercial fertilizers, "showing . . . the soil's need of vegetable matter and nitrogen." Rotation experiments proved cowpeas a very effective renovating crop for worn cotton soils.

At the Camden substation a complete fertilizer produced better crops of cotton and Whip-poor-will peas than incomplete fertilizers. Various fertilizers were applied to Spanish peanuts, but the crop was attacked by disease and part of the peanuts rotted, although "the acid phosphate and kainit plats were practically all sound."

A note is given on the value of soil tests with fertilizers.

**Composition of humus**, H. SNYDER (*Jour. Amer. Chem. Soc.*, 19 (1897), No. 9, pp. 738-744).—This is an abridgment of an article in Minnesota Station Bulletin 53 (see page 632).

## FERTILIZERS.

**The decomposition of nitrates by bacteria**, A. STUTZER and H. JENSEN (*Deut. Landw. Presse*, 24 (1897), No. 73, p. 665).—Experiments are reported which throw light on the behavior of denitrifying organisms in different kinds of manure, to which attention has recently been called by the work of Maereker and Wagner.<sup>1</sup> These experiments indicate that these organisms are incapable of reducing nitrates except in the presence of a sufficient supply of assimilable carbon compounds to supply energy. If such a source of energy is lacking the nitrates remain unaltered, although the denitrifying organisms may be present in abundance. The fact observed by Maereker that horse manure is more active in causing denitrification in the soil than the manure of sheep or cows is explained by the fact that horse manure is much richer in assimilable carbon compounds than the other manures. The mechanical condition of the horse manure also is such that it is more uniformly and rapidly distributed in the soil than the other kinds.

Samples of horse and cow manure were shaken up in water containing a small amount of nitrates, parallel series of tests being made, in one of which easily assimilable carbonaceous matter was added in the form of glycerin. It was observed that the horse manure without the addition of carbonaceous matter destroyed the nitrates much quicker

<sup>1</sup>Landw. Vers. Stat., 48 (1897), pp. 163-260 (E. S. R., 8, p. 872).

than the cow manure, and that the addition of glycerin resulted in a most marked increase in the activity of the denitrifying organisms in both kinds of manure. It was observed further that after a time denitrification ceased, although nitrates were still present, but it commenced again immediately on the addition of more glycerin.

The authors observed that when straw was put into a solution of nitrates the nitrates were destroyed but that denitrification did not start immediately. It was shown in this case by experiments similar to those reported above that the inactivity of the denitrifying organisms at the beginning was due to an insufficiency of assimilable carbonaceous matter. This was supplied to them only after the straw had undergone partial decomposition. When glycerin was mixed with the nitrate solution the denitrification began immediately on the immersion of the straw in the solution; or if partially decomposed straw was used denitrification began at once.

**Fertilizers** (*New Jersey Stas. Rpt. 1896, pp. 19-110*).—Most of the material in this article has already been published.<sup>1</sup> Statistics are given of the quantity and value of fertilizers used in New Jersey during 1895, comparing the trade of this year with that of preceding years. The market prices of various fertilizing materials are reviewed, with trade values of fertilizing ingredients for 1896, and analyses and valuations are given of 495 samples of fertilizing materials, including nitrate of soda, sulphate of ammonia, dried blood, dried and ground fish, tankage, ground bone, dissolved South Carolina rock phosphate, Thomas slag, muriate of potash, sulphate of potash, kainit, ashes, nitrate of potash from tobacco extracts, tobacco stems, marl, stone lime, crematory garbage, wool waste, sea pumpkin, and home-mixed and factory-mixed fertilizers.

A review of market prices of fertilizing materials for 7 years shows that the difference between wholesale and retail prices of nitrogen in 1895 was 26.5 per cent. "This is much wider than ever before and is largely due to the unusually low wholesale prices which ruled for all ammoniates during 1895. In the case of available phosphoric acid the difference has been diminished about 21 per cent, while in potash there is a slight increase of 1 per cent."

The following table shows the deficiencies of the various brands examined in 1895 and 1896:

*Agreement of actual composition with guaranteed composition of fertilizers, 1895 and 1896.*

Year.	Brands examined.	Found as guaranteed.	Found deficient.	Number of deficiencies.		
				Nitrogen.	Phosphoric acid.	Potash.
1895.....	269	158	111	17	72	37
1896.....	329	211	118	30	52	56

<sup>1</sup> New Jersey Stas. Bul. 117 (E. S. R., 8, p. 966).

Practically four-fifths of the brands of fertilizers examined contained as much total plant food as was guaranteed, but in many cases it was not distributed in the proportions claimed.

**The availability of organic nitrogen** (*New Jersey Stat. Rpt. 1896, pp. 110-117*).—Two artificial methods for determining the availability of organic nitrogen in fertilizing materials were tested, namely, digestion in acid pepsin solution<sup>1</sup> and treatment with permanganate of potash according to Hayes.<sup>2</sup>

The first was tested on 49 brands of commercial fertilizers, and on samples of bone sawings, steamed bone, cotton-seed meal, dried ground fish, tobacco dust, king crab (*Limulus polyphemus*), wool waste, hoof meal, and certain special mixtures of ground hoof, tankage, leather, ground horn, dried blood, sodium nitrate, ammonium sulphate, potassium chlorid, and acid phosphate.

Twelve per cent of the fertilizers examined showed a suspiciously low solubility of nitrogen (50 per cent and less). The results of the other tests "confirm on the whole the general belief that the nitrogen of ground bone, blood, cotton-seed meal, and high-grade tankage possesses a high degree of availability [77.1 to 94.5 per cent]; they also show that the nitrogen of dried fish, tobacco dust, king crab, and hoof meal is considerably less available [52.3 to 70.9 per cent], while that of wool waste, raw leather, and ground horn is of very inferior quality [14.9 to 29.9 per cent]."

The results of these tests are compared with those of vegetation experiments on maize and oats made by the Connecticut State Station in 1894 and 1895.<sup>3</sup> The data thus obtained show that—

"With the exception of raw leather, the pepsin method tends to give lower results than were secured by the vegetation tests. The pepsin results, however, are quite satisfactory, except in the case of hoof meal, where the pepsin solubility is nearly 23 per cent lower than by the actual culture test. These results, therefore, confirm the conclusions of other investigators, namely, that, in general, the solubility of the nitrogen of these samples in pepsin solution was a fairly good measure of the relative availability of the nitrogen to the plant under the conditions of the vegetation experiment." In hoof meal, however, the solubility of the nitrogen in pepsin solution is no indication whatever of its relative availability."

The Hayes method was tested on 4 samples of complete fertilizers; on dried blood, tankage, hoof meal, and raw leather in mixtures; and on dried fish and steamed bone alone. Two solutions were used, one prepared by dissolving 16 gm. of potassium permanganate and 200 gm. of potassium hydroxid in 1 liter of water, the other by dissolving 16 gm. of permanganate in 1 liter of 10 per cent sulphuric acid.

"The results secured both by the acid and alkali digestions are very satisfactory. When digested in alkali solution hoof meal and raw leather give too high results while in acid solution all agree closely in comparison with the vegetation tests,

<sup>1</sup> Connecticut State Sta. Rpt. 1893, p. 218 (E. S. R., 6, p. 130).

<sup>2</sup> U. S. Dept. Agr., Division of Chemistry Bul. 47, p. 112 (E. S. R., 8, p. 26).

<sup>3</sup> Connecticut State Sta. Rpt. 1895, p. 112 (E. S. R., 8, p. 387).

except steamed bone, which is too low. These results are too few for any definite conclusions to be drawn from them, but those secured by the acid digestion are very encouraging, and this method, possibly with some modifications, promises at least a partial solution of the problem of a laboratory method for determining the availability of organic nitrogen."

**Pond cleanings**, P. BRIDGE (*Farm and Home*, 16 (1897), No. 822, p. 425).—A note on pond and ditch cleanings as a top-dressing for pastures and how to apply them.

**Analyses of commercial fertilizers** (*South Carolina Sta. Bul.* 29, pp. 30).—Notes on valuation and on sampling, regulations regarding the sale of commercial fertilizers in South Carolina, and tabulated analyses and valuations of 272 samples of fertilizing materials, including mixed fertilizers, cotton-seed meal, and kainit.

**Fertilizer analyses**, B. H. HITE (*West Virginia Sta. Bul.* 46, pp. 408-432).—The text of the State fertilizer law, notes on valuation, and tabulated analyses and valuations of 480 samples of fertilizers.

## FIELD CROPS.

**The composition and yield of different varieties of sugar cane**, P. BONAME (*Rep. An. Sta. Agron. [Mauritius]*, 1896, pp. 16-33).—Experiments were carried on with 61 varieties of sugar cane. The total yields and the sugar content of each variety on August 5, September 8, and October 6 are here reported. Sandal, New Caledonian, and Stripped Java, in the order given, produced the largest amount of sugar per acre, while Setters, Tamarin, and Vilain contained the highest percentage of sugar—23.78, 23.06, and 22.98 per cent respectively, with 94.4, 93.3, and 91.1 as the corresponding coefficients of purity. The early maturing varieties showed but little variation in their sugar content from August to October as compared with the later ripening kinds, which continue to increase their sugar content until the time of the harvest.

**Experiments in breeding Noë summer wheat and Göttingen oats**, LIEBSCHER, EDLER, and VON SEELHORST (*Jour. Landw.*, 45 (1897), No. 3-4, pp. 211-263).—Pot experiments were made to determine the influence of selection of seed. Each experiment occupied 12 pots, only 3 of which received no fertilizer, the rest receiving equal amounts of chemical manures. Three of the pots containing the fertilized soil contained 8 plants each and 6 1 plant each, while in each of the 3 with the unfertilized soil 8 plants were grown. The results are given in detail in tabular form.

The results in the wheat experiments indicate that seed from large heads, so selected for a number of years, produces a greater total yield than seed similarly selected from small heads. The thickness and length of the straw and the length of the upper internode were found to be greater in the plants grown from seed taken from large heads, and the number of internodes was also somewhat greater. Seed taken from heavy-culmed plants produced a heavier, stronger, and somewhat longer straw than seed taken from thin-culmed plants. The number of nodes was also found to be hereditary. The progeny of 5-noded plants

produced a larger total crop, stronger and longer culms, and longer heads, than the progeny of 4-noded ones. The upper and fourth internodes were also longer and the heads heavier.

It was further observed that where 1 plant was grown in a pot a smaller yield was obtained than where 8 plants were grown on the fertilized soil and a larger yield than where 8 plants were grown on the unfertilized soil. The plants grown singly had a smaller number of internodes than the other plants. The authors conclude from this that growth in a well-lighted position favors the strengthening of the culm and reduces the number of internodes. The length of the upper internode was found to increase with the increase of strength in the culm and a decrease in the number of internodes, while with the lower internode the opposite took place. The length and the weight of the heads are considered to be dependent on vegetative conditions.

The experiments with Göttingen oats indicated that in general the number of internodes, the weight of the grain, and the number of grains in the head are not transmitted to the progeny. The 8 plants grown in the pot with fertilized soil gave the largest total yield, followed by the single plants and the 8 plants grown on unfertilized soil in the order mentioned. The panicle produced by the single plant was heavier than the panicles of the 8 plants grown in one pot, and the panicles produced on the fertilized soil were heavier than those grown on the unfertilized soil.

**Wheat** (*Kentucky Sta. Bul. 69, pp. 79-96, pls. 3*).—A test of 17 varieties of wheat was made. The meteorological conditions of the season and the results obtained from the variety tests are given in tables. Bearded Winter Fife heads the list in productiveness, having yielded 30.5 bu. per acre, and proves to be one of the heaviest, a bushel weighing 63 lbs. The variety is also considered worthy of special attention on account of its milling quality. Besides this variety, Oatka Chief, Pedigreed Early Genessee Giant, Early Arcadian, and White Golden Cross yielded more than 25 bu. per acre. Early White Leader, Jones Bearded, and Diamond Grit are not considered good for milling purposes.

A synopsis and detailed description are given of each variety by the botanist of the station. A representative head of each variety is figured and directions given for treating wheat with hot water and blue-stone solutions as remedies for smut.

**Influence of the nature of soil on the culture of wheat** (*Rev. Sci. [Paris], 4. ser., 8 (1897), No. 16, p. 504*).—Conclusions based upon the results of experiments are given. For best yields on humus soils seed grown on argillaceous soils is advised to be used, while on sandy lands seed from a calcareous region, and on calcareous or argillaceous soil seed from a sandy soil is recommended. It is stated that the smallest yields are obtained on humus soils from seed taken from a humus or a calcareous soil; on sandy lands from seed grown on land of the same

texture or on a humus soil, and on calcareous soils from seed obtained from calcareous or humus lands.

**Experiments with chemical manures**, J. R. BOVELL and J. P. D'ALBUQUERQUE (*Rpt. Expt. Fields Dodd's Reform. [Barbados], 1896, pp. 2-30*).—This is a comparison of varieties of sugar cane and a study of the influence of chemical fertilizers on the yield and the chemical composition of the crop. Similar work has been reported in former publications (*E. S. R.*, 8, p. 394). The previous history of the field and the mechanical and chemical analyses of the soils are given. All results are in tabular form. The authors summarize the results obtained in one of the fields as follows:

“The addition of readily available nitrogen to mineral manures produced a large increase in the weight of canes and in the yield of available sugar in the juice; the most advantageous amount being sulphate of ammonia 60 lbs. per acre of nitrogen; a larger application was followed by a marked diminution of yield.

“That the application of nitrogen in the form of such slowly decomposing organic matter as dried blood, added to mineral manures, produced a large increase in the weight of canes and yield of available sugar in the juice, and that such application of organic nitrogen (up to the equivalent of 60 lbs. nitrogen per acre) was applied with greatest advantage during the earlier stages of cane growth.

“That nitrogen in the form of sulphate of ammonia was superior as a source of nitrogen to nitrate of soda.

“The yield of available sugar was increased by the addition of 100 lbs. phosphate per acre in the form of finely ground basic slag carefully applied during the early stage of the canes' growth. The application of superphosphate led to diminished yields, probably due to the poverty of this soil in carbonate of lime.

“The addition of sulphate of potash to manuring of nitrogen and phosphates produced large increase in the yield of cane and of available sugar in the juice per acre.

“An application of sulphate of potash at the rate of 60 lbs. potash per acre applied during the early stage of cane growth produced the best result.”

**Lime and liming**, H. J. WHEELER (*Rhode Island Sta. Bul. 46, pp. 85-109*).—This bulletin reports the results of experiments conducted at the station during the last 4 years to ascertain the effects of liming upon the growth of various plants, including field, garden, and forage crops. The recent experiences of practical farmers who used lime as a fertilizer and soil improver are given, and the chemical and physical effects of lime when applied to the soil are discussed. The different forms of lime for fertilizing purposes are noted, and methods for their application recommended.

The author recommends the application of lime to be made in the field by sowing the lime after plowing and then thoroughly incorporating it into the surface soil by means of a harrow. It is regarded best not to lime just before growing a crop of corn, rye, or millet, as lime when first applied is usually more or less caustic, and in this state is liable to injure the crops, especially when the soil conditions induce rapid nitrification of the soil nitrogen or the nitrogen applied in natural and artificial manures. “If the soil is very sour and nitrates are not employed, then the use of lime immediately before these crops may prove of great service. . . . Under all circumstances lime should be

harrowed in immediately or it is liable to cake with the soil and will not yield the best results." It has been found that for vegetables lime may be applied to great advantage in the spring.

The quantity of lime to be applied on light, dry, sandy soils is given as  $\frac{1}{2}$  to  $1\frac{1}{2}$  tons per acre, and on heavier soils as 1 to 3 tons. One application during a rotation lasting from 5 to 7 years is considered adequate.

Liming experiments with clover and grasses, conducted in different parts of the State, resulted in a marked benefit to these crops.

In 124 instances during the 4 years the experiments were made at the station limed soil was more productive, and in 33 cases less productive, than unlimed land.

In a calculation the author shows that the plant food in wood ashes at \$11 per ton is more expensive than plant food in the form of lime and chemicals.

Attention is called to the fact that lime favors the growth of the potato-scab fungus, and a description of the corrosive sublimate and formalin treatments against this disease is given.

**Effects of the rotation of crops upon humus content and the fertility of soils, II.** SNYDER (*Minnesota Sta. Bul. 53, pp. 1-11*).—A field which had produced small grain for about 40 years was divided into 6 plats of quite uniform-fertility and studied for 4 years.

The cropping during the 4 years was as follows:

Plat 1, wheat continuously.

Plat 2, wheat in 1893, clover in 1894, wheat in 1895, and oats in 1896.

Plat 3, oats in 1893, clover in 1894, barley in 1895, and corn in 1896.

Plat 4, corn continuously.

Plat 5, oats continuously.

Plat 6, barley continuously.

The different crops were sampled and analyzed and analyses were made of the upper 9 in. of the soil before and after the experiment. Only 2 plats received humus-forming materials (manure and clover).

At the beginning of the experiment the soil of plat 1 contained 0.221 per cent of nitrogen and after 4 years of continuous wheat growing 0.193 per cent, or a decrease of 0.028 per cent, amounting to an annual loss of 171 lbs. of nitrogen per acre. During the 4 years 98 lbs. of nitrogen per acre were removed in the crop, showing that each year about 146 lbs. of nitrogen were lost from the soil above the amount removed in the crop. "This nitrogen was lost by the oxidation of the humus, by denitrification, mechanically, by wind storms, and through the loss of nitrates by drainage." The author refers to previous work of the station (E. S. R., 5, p. 867) showing that wheat takes over 85 per cent of its nitrogen from the soil during the first 50 days of growth. "Inasmuch as there is only this short period of 50 days when the nitrogen is mainly utilized by the wheat crop, while the breaking down of the humus goes on during 7 or 8 months of the year, it is easy to understand why there is such a heavy loss of nitrogen when a grain crop is raised continuously as on this plat,"

In plat 2, where clover was grown in rotation and its second crop plowed under for green manure, the soil originally contained 0.221 per cent of nitrogen and at the end of the rotation 0.231 per cent. Larger crops were grown on this plat than on plat 1, and 178 lbs. of nitrogen was removed in the crops, yet there was a gain of 245 lbs. of nitrogen during the 4 years, in addition to the amount removed. "This nitrogen, it is believed, has been gained largely by the clover from the free nitrogen of the air. . . . The value of a good rotation is exemplified in this experiment where the yields per acre have been increased, and at the same time both the humus and the nitrogen have been increased."

On plat 3 the clover was seeded with oats instead of with wheat as on plat 2. The clover crop, which was rather light, was followed by barley. After the barley crop, this plat received 1,200 lbs. of manure and the next year was seeded to corn, yielding 17 bu. per acre more than plat 4 where corn was grown continuously.

The soil of plat 4 originally contained 0.211 per cent of nitrogen and, after the 4 corn crops were grown 0.197 per cent, amounting to a loss of 340 lbs. of nitrogen. In the 4 crops 225 lbs. of nitrogen were removed, or nearly 29 lbs. more nitrogen was lost from the soil each year than were removed in the crop.

During 4 years of continuous oat growing on plat 5 there was an annual loss of 196 lbs. of nitrogen per acre, of which only about 46 lbs. per acre were removed by the crop. The author states that the yield has been less affected, although this plat lost its nitrogen more rapidly than plat 1, because the oat plant is a stronger feeding plant than wheat.

On plat 6 the soil contained 0.211 per cent of nitrogen, and after 4 years of continuous barley culture 0.177 per cent, showing a total loss of 800 lbs. of nitrogen. It is reported that about 30 lbs. of nitrogen were annually removed by the crop, and that there was an annual loss of 190 lbs. of nitrogen per acre in addition.

It is stated that before the rotations there was an average of about 3.30 per cent of humus and 7.68 per cent of total volatile matter in the soil. The percentages of humus and volatile matter at the close of the rotation periods are given in the following table:

*Loss and gain of humus.*

	Humus.	Gain (+) or loss (-).	Total volatile matter.	Gain (+) or loss (-).
	<i>Per cent.</i>		<i>Per cent.</i>	
Plat I. Wheat continuously .....	3.00	-0.30	7.48	-0.20
Plat II. Rotation .....	3.80	+ .50	8.05	+ .37
Plat III. Rotation .....	3.50	+ .20	7.83	+ .15
Plat IV. Corn continuously .....	3.10	- .20	7.26	- .42
Plat V. Oats continuously .....	3.08	- .22	7.04	- .54
Plat VI. Barley continuously.....	3.10	- .20	6.87	- .81

With continuous wheat raising an annual loss of 1,800 lbs. of humus per acre, and with the continuous culture of corn, oats, and barley, an annual loss of 1,500 lbs. per acre is reported.

The loss of humus affected the physical qualities of the soil, especially the color and the weight. The soils from plats 2 and 3 were darker than those from the other plats and lost in weight while the other soils became heavier.

A strip of land was summer fallowed for 2 years. Before the summer following the soil contained 0.221 per cent of nitrogen and after 2 years 0.201 per cent. The author states that in summer fallowing too much of the nitrogen is changed to available forms and then, as the following crop can not use it all, a large percentage is lost. "While a loss of 0.02 per cent of nitrogen does not appear to be a heavy one, it is in the aggregate quite large, as it amounts to 590 lbs. of nitrogen per acre. Two wheat crops would have removed less than 100 lbs. of nitrogen."

**Our grains and field flowers**, B. PLÜSS (*Unsere Getreidearten und Feldblumen. Freiburg i. B.: Herder, 1897, pp. 204, figs. 200*).—A description of the grains, the most important forage plants, and the flowers commonly occurring in fields and meadows.

**Field trials with artificial fertilizers**, K. HANSEN (*Landmansblade, 30 (1897), Nos. 24, pp. 322-327; 25, pp. 340-342*).

**Cereal plants: Rye, mixed grain, barley, oats, buckwheat, millet, panicum, and maize**, G. HEUZÉ (*Les plantes céréales. II Seigle, meteil, orge, avoine, sarrasin, millet, panis et mais. Paris: Maison Rustique, 1897, 2. ed., pp. 376, figs. 84*).

**The essential properties of good malting barley**, P. BOLIN (*Landmannen, 8 (1897), No. 38, pp. 534-538*).

**Cañaigne** (*U. S. Dept. Agr., Office of Experiment Stations Circ. 25, pp. 4, fig. 1*).—This is a revision of Circular 25. A description of the plant is given, with notes on its tannin content and directions for its culture and preparation for market. The States in which it is grown are mentioned and its industrial importance pointed out.

**Broom corn** (*U. S. Dept. Agr., Office of Experiment Stations Circ. 28, pp. 4*).—This is a revision of Circular 28 (E. S. R., 9, p. 241). The varieties of broom corn; the climate, soil, and manuring requisite for its successful culture; and its feeding value are discussed; and directions are given for planting, cultivating, harvesting, and curing.

**Flax, its culture and use, with suggestions for the improvement of the industry**, R. KUHNERT (*Der Flachs, seine Kultur u. Verarbeitung, nebst Vorschlägen zur Hebung des Flachsbanes. Berlin: Paul Parey, 1897, pp. 198, figs. 40*).

**Pasture and pasture plants**, W. TOOGOOD (*New York: The Macmillan Co.; London: Macmillan & Co. Ltd., 1897, pp. 72, figs. 35*).—In the compilation of this treatise the chief aim of the author has been to concisely summarize his own experiences in pasture-making, but the recorded experiences of great authorities on the subject have also been consulted and form, to some extent, the basis of the work. The book contains 9 chapters in which cultural preparations, selection of pasture plants, buying, testing, and sowing of pasture seeds, and the care of new and of established pastures are discussed, and 20 varieties of grasses and 9 varieties of legumes useful as pasture plants are described.

**The renewing of worn-out native prairie pastures**, T. A. WILLIAMS (*U. S. Dept. Agr., Division of Agrostology Circ. 4, pp. 4, figs. 4*).—A revision of Circular 4 (E. S. R., 8, p. 774).

**Comparative experiments with 190 varieties of potatoes to determine the starch production, at the agricultural-botanical experiment station at Tabor [Bohemia] in 1896**, F. SITENSKÝ (*Časopis pro Průmysl Chemický, 7 (1897), pp. 253, 279; abs. in Chem. Ztg., 21 (1897), No. 95, Repert., p. 289*).—According to the brief abstract, the starch content varied from 9.6 to 19 per cent, and the yield of starch per hectare from 1,282 to 6,386 kg. (1,141 to 5,684 lbs. per acre).

**Culture tests with new varieties of potatoes** (*Tidskr. Landtmän*, 18 (1897), No. 12, pp. 204-209).—Trials with 36 varieties of potatoes containing from 14.1 to 24.6 per cent of starch, and yielding 9,820 to 26,420 kg. of tubers per hectare, and 2,268 to 6,063 kg. of starch.

**Potash fertilizers for root crops and barley**, H. NATHORST (*Tidskr. Landtmän*, 18 (1897), No. 6, pp. 91-95).

**Sugar beet culture**, S. FORSBERG (*Tidskr. Landtmän*, 18 (1897), No. 9, pp. 153-157).

**The influence of the distance between plants on the yield and sugar content of sugar beets**, F. DESPREZ (*Jour. Agr. Prat.*, 2 (1897), No. 48, pp. 816-819).—A number of plats were planted with beets at the rate of 16.6, 12.5, 10, and 8.3 plants per square meter. The largest amount of sugar per hectare was obtained from the closest planting.

**The state of cane sugar manufacture in Formosa**, N. YAMASAKI (*Imp. Univ. Col. Agr. [Tokyo] Bul.*, vol. 3, No. 3, pp. 275-280).—A description of the industry as it is carried on in the island.

**Silage making according to the Rahmstedt method** (*Landtmannen*, 8 (1897), No. 38, pp. 540-542).

**Tobacco from the seed bed to the packing case: The result of three years' experience in southern California with plain practical directions for the grower on the Pacific Coast, Arizona, and New Mexico**, W. T. SIM (*Los Angeles: Stoll, Thayer & Co.*, 1897, pp. 26).

**Report of the assistant in dairy husbandry**, C. B. LANE (*New Jersey Stat. Rpt.* 1896, pp. 171-181, pl. 1).—This is a brief description of the college farm; the yield and cost of rye, wheat, crimson clover, oats and peas, corn, cowpeas, soy beans, and barley and peas grown as silage crops; a description and record of the dairy herd; methods of seeding crimson clover; and a description of an experimental silo.

**Marsh culture, and the manufacture of peat litter and peat fuel in Sweden, Denmark, and Germany**, H. U. SVERDRUP (*Aarsber. Offent. Foranst. Landbr. Fremme*, 196, pp. 342-391).

## HORTICULTURE.

**Some problems in experimental horticulture**, W. M. MUNSON (*Vermont Hort. Soc. Rpt.* 1896, pp. 32-40).—The author believes that, while it is the first duty of an experiment station to adapt its work to the specific needs of the region in which it is located, the working out of fundamental principles should not be ignored. A certain amount of variety testing, for instance, is of value, but it should not be made the chief work of the station. One of the most important lines of work, the author believes, is plant breeding, and in this work a very important thing is to determine the causes of variation in plants and how generally variations are transmitted to offspring. In crossing and hybridizing the aim should be to study the laws governing hybrids as well as to produce new types of immediate value. The pedigree should be given more weight in plant breeding than it has yet been given. As corollaries to plant breeding, acclimatization, domestication, etc., are discussed.

Among the practical problems of experimental horticulture, the author suggests the treatment of orchard and small fruits with reference to culture, pruning, food, winter protection, etc.; the merits of various stocks for grafting certain varieties; the origin and development of new varieties of fruits and vegetables; the questions relating

to forcing fruits and vegetables; and the like. Vegetables and ornamental gardening are mentioned as affording valuable lines of work.

**Depth of sowing and planting**, B. D. HALSTED (*New Jersey Stas. Rpt. 1896, pp. 395, 396*).—Beet seed covered 4 to 6 in. failed to germinate. There was little difference in results from seed planted 2 in. and 1 in. deep. With beans about one-half as many seed germinated in the 6 in. planting and about two-thirds as many in the 4 in. planting as in the 1 in. planting. Beans, when planted 4 and 6 in. deep and the drills filled gradually as the plants developed, germinated as well as those planted at the ordinary depth, and the yield was practically the same in all cases. With potatoes planted 4, 6, and 8 in. deep, the 6 in. planting gave the largest yield, also the greatest percentage of scab, while the 4 in. planting gave the smallest yield and percentage of scab.

**Experiments with mulching**, B. D. HALSTED (*New Jersey Stas. Rpt. 1896, pp. 393-395*).—Mulchings of fresh hay, salt hay, and excelsior were employed with several vegetables. There was no appreciable difference in yield of peppers, eggplants, cucumbers, tomatoes, beets, and second crop of beans between the mulched and unmulched rows. The mulched rows of the first crop of beans gave a somewhat larger yield than the unmulched. The difference between the results here reported and those of 1895 (E. S. R., 8, p. 886) the author believes to be due to the greater rainfall in 1896. Salt hay was found better for mulching than either of the other materials tried.

**Irrigation of garden crops**, B. D. HALSTED (*New Jersey Stas. Rpt. 1896, pp. 338-383*).—This is a continuation of the experiment reported in Bulletin 115 of the station (E. S. R., 8, p. 127), a summary of which is given in this report. The quantities of water applied to the various crops and the dates of the applications are shown in tables. With a majority of the crops irrigation in a season of normal rainfall was found to be unprofitable.

The yield of the first crop of peas was increased nearly 30 per cent and the weight of the vines doubled by irrigation. In the second crop the weight of the vines on the irrigated plat was somewhat less than on the others. Few pods developed in either case on account of blight. Tomatoes yielded less, the fruit was more spotted and more cracked in the irrigated than in the unirrigated plats. As to the prevalence of leaf blight, little difference could be seen between the irrigated and the unirrigated plats.

Irrigation had little effect on the yield of beans, peppers, cucumbers, beets, turnips, and eggplants; on the amount of scab and blight of beets; and on the amount of leaf blight and fruit rot of eggplants. The proportion of turnips affected with club root was about the same in the two cases, but the affected roots were somewhat more severely injured on the irrigated than on the unirrigated plats. The amount of bacterial blight of beans was somewhat greater in the case of the unirrigated than of the irrigated plants.

In the experiment with Rural No. 2, American Giant, and Early

Rose potatoes, the yield was 9 per cent greater and the amount of scab slightly less on the irrigated plants than on the unirrigated ones. In another test, irrigation did not appreciably affect the yield or percentage of scab of Rural No. 2 potatoes. With American Giant potatoes, the yield and amount of scab was greater on the irrigated plats than elsewhere. The yield of Early Rose potatoes was considerably greater and the scabbiness from 19 to 27 per cent less on irrigated than on unirrigated plats. A test of both surface and subirrigation with Early Rose potatoes resulted in no difference in yield and very little difference in scabbiness between the irrigated and the unirrigated plants.

**Studies and illustrations of mushrooms, I, G. F. ATKINSON** (*New York Cornell Sta. Bul. 138, pp. 337-366, figs. 26*).—This is the beginning of a proposed series of bulletins on the fleshy fungi of the mushroom family. The author briefly discusses the need of a more general knowledge of the more common mushrooms in order that the nutritious ones may be used and the poisonous ones avoided. He believes that many common forms of mushrooms may be learned by people without a technical knowledge of the subject, just as many other natural objects are known.

Popular descriptions and illustrations are given of *Agaricus campestris*, *Lepiota naucina*, and *Amanita phalloides*, showing the peculiarities of the plants at various stages of growth. The life history of mushrooms is also given in a popular way.

**Turnips, F. S. EARLE** (*Alabama College Sta. Bul. 84, pp. 415-420*).—Directions for planting and culture and a note on the uses of turnips are given. About 40 varieties of turnips, many of them foreign, were tested at the station. The foreign varieties were found to be no better than varieties commonly grown in this country. The flat varieties of turnips are valuable for early crops and marketing when young. The long varieties have nothing in particular to recommend them. The Globe varieties are best for the main crop and for fall and winter use. For late winter the Yellow Globes are especially recommended. The flat and the long varieties, on account of much of their roots being exposed, are often rendered unfit for use by being frozen. The Globe varieties have a deep rooting habit and therefore are least injured by freezing.

**Notes on the cherry orchard, W. B. ALWOOD** (*Virginia Sta. Bul. 65, pp. 69-71*).—Notes are given on 22 varieties of cherries, together with a table showing the dates of bloom of each for the years 1893-'97. The following varieties are thought worthy of general culture for market and family use: Early Purple, Schmidt, Windsor, Hortense, Olivett, and Montmorency Large.

In a situation so exposed to late spring frosts that peaches can not be grown, that Japanese plums can not fruit, and that apples fruit only once in 2 or 3 years, the Hearts, or sweet cherries, as a class have failed to fruit, although the trees have proved hardy in many cases. Both Hearts and Morillos are more readily grown than peaches in situations where the latter succeed.

**Notes on the plum orchard**, W. B. ALWOOD (*Virginia Sta. Bul. 67, pp. 93-97*).—Tabular data in regard to dates of blossoming of 37 varieties of plums for the years 1893-'97 are given, together with notes on growth, fruitfulness, etc. The Japanese varieties have proved somewhat erratic as to time of blossoming, being stimulated into unseasonable bloom by a few warm days. As a preventive of brown rot, the author recommends removing all decayed fruit from the tree as soon as the leaves have fallen, and spraying in the spring before the buds start with a solution of concentrated lye, 8 cans to 50 gal. water, or with a solution of copper sulphate, 2 lbs. to 50 gal. water, the lye solution being preferred, and spraying twice with a weak Bordeaux mixture just before the flower buds open and again when the blossoms have fallen.

**Japanese plums**, F. S. EARLE (*Alabama College Sta. Bul. 85, pp. 423-448, figs. 5*).—The bulletin is a popular discussion of the culture of the Japanese plums, including notes on soil, fertilizers, propagation, planting, cultivation, pruning, thinning, marketing, insect enemies, diseases, and varieties. The author believes that the Japanese plums are destined to supersede the native plums in Alabama. Tendency to overbear is considered their greatest fault, the fruits often setting so thick as to hide the limb from view. Thinning the fruit is therefore strongly recommended. It increases the size of the fruit, lessens the injury from rot, and prevents the loss of vitality of the tree. An illustration is given of two twigs of Burbank plum, showing the increased size of fruit due to thinning.

The most reliable remedy for the plum curculio is jarring the tree. Descriptions are given of two modifications of the "curculio catcher" for low-headed trees. Trapping the beetles under pieces of bark placed around the trees, destroying all fallen, wormy fruit, and spraying the trees with Paris green are also recommended.

Plum rot is the most troublesome disease of plums. The remedies recommended are planting resistant varieties, selection of high, well-drained soil of moderate fertility, use of only such fertilizers as will not induce a rapid, succulent growth of wood, training the trees with open heads to allow free circulation of air, thinning the fruit, burning dead twigs and mummified fruits in winter, and spraying with Bordeaux mixture in spring and with copper acetate after the fruit is formed.

**Strawberry culture**, S. POWERS (*Florida Sta. Bul. 39, pp. 465-504*).—This is a popular bulletin giving directions for growing and marketing strawberries. A good quality of flat-woods soil, overlying a clay subsoil and having a gradual slope to the south, is recommended. Light sandy soils are to be avoided except where an abundance of water is available. The plants grow practically all winter, and should therefore be allowed to rest during midsummer, no cultivation being given them.

The author believes that the deterioration of strawberries in Florida is due to careless methods of propagation and cultivation more than to

the climate. To get new vitality, plants may be brought from the foothills of Alabama or Georgia. Plants brought from States north of the Potomac and Ohio rivers do not succeed in Florida.

Notes are given on the diseases and insect enemies of the strawberry. A brief paper by C. H. Ward is added to the bulletin.

**Catalogue of fruits recommended for cultivation in the various sections of the United States by the American Pomological Society** (*U. S. Dept. Agr., Division of Pomology Bul. 6, pp. 39*).—The catalogue includes such fruits and nuts as are recommended for culture in the United States and adjoining parts of British America. The entire region is divided into 15 fruit districts, the limits of districts being determined largely by latitude, elevation, prevailing winds, oceanic and lacustrine exposures, and very little by political boundaries.

For convenience in reference the fruits are arranged alphabetically in 3 divisions. The first division deals with fruits adapted to the middle and northern United States and adjacent parts of British America, and includes 277 varieties of apples, 12 apricots, 20 blackberries and dewberries, 41 cherries, 20 currants, 14 gooseberries, 88 grapes, 4 mulberries, 94 nectarines and peaches, 95 pears, 90 plums, 8 quinces, 48 raspberries, 35 strawberries, and 69 nuts. The second division has to do with fruits adapted to southern United States and includes 104 varieties of citrus fruits, 11 figs, 7 guavas, 11 Japanese persimmons, 28 olives, 18 pineapples, and 5 pomegranates. In both these divisions descriptions of each fruit recommended and the adaptability of each to the various fruit districts are given in tabular form.

The third division treats of such species of native and introduced fruits and nuts as have not varied so far from their specific types that the varieties have been designated and propagated under recognized varietal names. The botanical and common names, origin, and adaptability of 145 species of fruits, and 30 species of nuts are given in tabular form.

The bulletin also contains the rules of the American Pomological Society for naming and exhibiting fruits.

**Experience in fertilizing potted plants with Wagner's solution**, W. E. BRITTON (*Gard. and Forest, 10 (1897), No. 508, p. 456*).—The effect of a liquid fertilizer on various potted plants was tested at Connecticut State Station. The fertilizer consisted of a solution of 30 gm. ammonium phosphate, 25 gm. sodium nitrate, 25 gm. potassium nitrate, and 20 gm. ammonium sulphate in 100 liters of water. One lot of plants, 2 each of begonias and pelargoniums and 4 of heliotrope, was potted in rich soil, 3 parts turf and 1 part manure, and watered with clear water. Another similar lot was potted in the same soil and watered with the liquid fertilizer noted above. A third lot of plants was potted in anthracite coal ashes, to which was added 5 per cent of moss peat, and watered with the fertilizer solution. In a few months the plants were repotted. Their growth was greatest in the rich soil watered with the fertilizer

solution. The root development was very good in the rich soil given clear water, much smaller in the rich soil given the liquid fertilizer, and very small in the ashes and peat. About a month later, some of the pelargoniums given the liquid fertilizer wilted even while the soil was saturated with moisture. The plants were apparently very thrifty until they began to wilt. The author believes that "the amount of easily available nutritive matter in the soil exercises a considerable influence upon the size of the root system." Further work showed that the use of the solution gave excellent results when applied less frequently, once a week for woody plants and twice a week for rapid growing, herbaceous ones.

**The camphor tree**, L. H. DEWEY (*U. S. Dept. Agr., Division of Botany Circ. 12, pp. 7, figs. 2*).—A description is given of the camphor tree and the following points in regard to it are noted: Native range; range under cultivation; uses; conditions of successful cultivation; methods of propagation, planting, and cultivation; distillation of camphor; outlook for future market, etc.

**Fertilization of house plants**, C. ENGELSKJÖN (*Om rore Potteplanter (Gjödning. Christiania, 1897, pp. 42)*).

**Practical handbook of asparagus culture**, J. BÖTTNER (*Praktisches lehrbuch des spargelbaus. Frankfurt a. Oder: Trowitzsch u. Sohn, 1897, pp. 100, figs. 40*).—This treats of planting, manuring, harvesting, forcing, varieties, diseases, and insect enemies of asparagus.

**How to grow melons for market**, W. A. BURPEE (*Philadelphia: W. Atlee Burpee & Co., 1897, 8. ed., pp. 81, figs. 25*).—The book is a compilation of three prize essays, to which the experience of the editor is added. Details of growing and marketing muskmelons and watermelons and lists of approved varieties are given.

**Observations on recent cases of mushroom poisoning in the District of Columbia**, F. V. COVILLE (*U. S. Dept. Agr., Division of Botany Circ. 13, pp. 21, figs. 21*).—The circular notes recent cases of mushroom poisoning and urges greater caution in the selection of mushrooms for table use. Illustrations and popular descriptions of a number of mushrooms occurring commonly in the District of Columbia are given, including 5 edible species—the common mushroom (*Agaricus campestris*), the horse mushroom (*A. arvensis*), the shaggy mushroom (*Coprinus comatus*), the puff ball (*Licoperdon cyathiforme*), and the fairy ring mushroom (*Marasmius oreades*); and 2 poisonous species, the fly amanita (*Amanita muscaria*) and the death cup (*A. phalloides*).

**Report of the assistant in horticulture**, J. T. JORDAN (*New Jersey Stas. Rpt. 1896, pp. 160-169*).—An outline of the horticultural work in progress at the station is given. A detailed account is given of the treatment of the various experimental plats of fruits and vegetables.

**Improved breeding in plant and animal life**, A. G. LUCAS (*Trans. Iowa State Hort. Soc., 31 (1896), pp. 177-183*).—The author discusses some analogies of plant and animal life and believes that the principles of animal breeding may be applied by the horticulturist in the improvement of plants.

**Production of new hardy fruits by crossing and hybridizing**, J. L. BUDD (*Trans. Iowa State Hort. Soc., 31 (1896), pp. 260-262*).—Notes are given on the facilities for making crosses, the advances already obtained, and the minutiae of doing the work.

**Catalogue of fruits** (*Proc. 20th An. Meeting Georgia State Hort. Soc., 1896, pp. 77-94*).—Descriptions and notes of various fruits and indications of their adaptability to various sections of the State of Georgia are given in tabular form. The fruits considered are apples, peaches, nectarines, apricots, pomegranates, pears, plums, grapes, strawberries, raspberries, blackberries, mulberries, cherries, quinces, and

figs. Descriptive notes are also given on various varieties of walnuts, pecans, chestnuts, almonds, filberts, Japanese plums, and Japan persimmons.

**Handbook of Swedish pomology**, O. ENEROTH (*Handbok i svensk Pomologi. New ed., rev. and enl. by A. Smirnoff. Stockholm: Norstedt & Söner, vols. 2).*

**Russian apples**, J. B. MITCHELL (*Trans. Iowa State Hort. Soc., 31 (1896), pp. 265-269*).—The adaptability of the Russian apples to Iowa is discussed and descriptive notes are given on 56 varieties fruited by the author.

**The russets of Maine**, Z. A. GILBERT (*Trans. Maine State Pom. Soc., 1896, pp. 76-90, pls. 5*).—Notes on some russet apples, with descriptions of 10 varieties and illustrations of 5.

**The garden of citrus fruits**, C. MANCINI (*Il giardino d'agrumi. Casale: C. Casalone, 1897, pp. 238*).—A monograph on the cultivation of citrus fruits in Italy.

**Notes on peach culture**, J. H. HALE (*U. S. Dept. Agr., Division of Pomology Circ. 3, pp. 8, figs. 4*).—This is a revised reprint of an article in the Report of the Pomologist for 1894.

**Is the Satsuma plum self-sterile?** (*Rural New Yorker, 56 (1897), No. 2492, p. 710*).—A statement from C. E. Clark, Newark, New York, indicates the possible self-sterility of this plum. The orchard contained 25 trees each of 4 varieties of Japanese plums, each variety being in a block unmixed with other varieties. Abundance and Burbank plums set fruit very abundantly, Chabot set less fruit, and Satsuma set very little. The Satsuma trees in the rows next to Burbank and Chabot trees fruited well, those in the second rows fruited less, those in the third rows fruited very little, and those in the corner farthest from the other varieties bore no fruit at all.

**Prune culture in the Pacific Northwest**, E. R. LAKE (*U. S. Dept. Agr., Division of Pomology Circ. 2, pp. 7, figs. 3*).—A revised reprint of an article in the Report of the Pomologist for 1894.

**Currants and gooseberries**, W. M. MUNSON (*Trans. Maine State Pom. Soc., 1896, pp. 146-152*).—A popular article which treats of soil, propagation, culture, pruning, and training, varieties, insects, and diseases of currants and gooseberries.

**Strawberries, variety tests of 1896**, H. N. STARNES (*Proc. 20th An. Meeting Georgia State Hort. Soc., 1896, pp. 25-28*).—A report of a test of 80 varieties of strawberries at the Georgia Station.

**Grapes** (*Rural New Yorker, 56 (1897), No. 2499, pp. 822, 823*).—A résumé of 20 years' experience with various varieties of grapes at Farningdale, Illinois.

**Nut culture**, H. M. ENGLE (*U. S. Dept. Agr., Division of Pomology Circ. 1, pp. 4*).—A reprint of an article in the Report of the Pomologist for 1894.

**Carnations at the Cottage Gardens, Queens, New York** (*Florists' Exchange, 10 (1898), No. 1, pp. 10, 11*).—Notes on a number of varieties of carnations.

**The hardy species of clematis**, W. J. BEAN (*Garden, 52, No. 1362, pp. 499-503, figs. 4*).—Descriptive notes on 36 species of clematis.

**Crossing chrysanthemums**, G. P. RAWSON (*Florists' Exchange, 9 (1897), No. 52, p. 1174*).

**Hackberries as ornamental and shade trees**, J. SCHNECK (*Meehan's Mo., 7 (1897), No. 12, pp. 231, 232, figs. 4*).—Illustrated notes are given of *Celtis occidentalis* and *C. mississippiensis*.

**Lawns and gardens, how to plant and beautify the home lot, the pleasure ground, and garden**, N. J. ROSE (*New York and London: G. P. Putnam's Sons, 1897, pp. 414, pl. 1, figs. 172*).—The first part treats of the principles and practices of landscape art with chapters on the following topics: The study of natural scenery, implements, the plan, grading, drives and walks, grouping and massing trees and shrubs, detached groups and specimen plants, the proper use of herbaceous plants, the lawn, rocks and water, flower beds and borders, hedges, buildings, etc. The second part treats of the best hardy ornamental plants for the temperate zone of North America, under the following chapter heads: Deciduous trees, coniferous trees, flowering trees, ornamental shrubs, creepers and vines, and herbaceous plants. The numerous plans and illustrations are prepared by the author.

**Experiments with lawn grasses**, B. D. HALSTED (*New Jersey Stas. Rpt. 1896*, pp. 400, 401, fig. 1).—A report is given of a limited trial of meadow fescue, five leaved fescue (*Festuca tenuifolia*), sheep's fescue, Rhode Island bent, wood meadow grass, Kentucky blue grass, rough stalked meadow grass, reedtop, and rye grass. All plots were treated alike and all seed gave a comparatively good stand except the second and third varieties.

**Orchid culture** (*Amer. Florist*, 13 (1897), No. 499, pp. 521, 522).

**The Horticultural School in Rentglingen and horticulture in southern Germany**, H. MISVAER (*Norsk Havetidende*, 13 (1897), No. 2, pp. 17-33).

**Europe's largest horticultural school**, L. SPÄTH (*Sv. Trädgårdsför. Tidskr.*, 1897, Nos. 2, pp. 19-24; 3, pp. 40-44).

## FORESTRY.

**Age of trees and time of blazing determined by annual rings**, B. E. FERNOW (*U. S. Dept. Agr., Division of Forestry Circ. 16*, pp. 11, figs. 12).—The author discusses the growth of trees and the method of deposition of annual rings, and points out some of the sources of error in estimating the age of trees by counting the annual rings.

To find how many years have elapsed since a cut was made it is necessary to have a cross section or part of a cross section of a stem that embraces a radius of the trunk near the wound, then the number of rings may be counted from bark to pith, and the particular ring leading to the edge of the wound may be traced from the wound to the radius along which the counting is done. This method is generally correct to within about half a year, but at times may result in an error of a whole year.

**Notes on cultivated conifers, XIII**, C. S. SARGENT (*Gard. and Forest*, 10 (1897), No. 514, pp. 509-512).—Notes are given on various species of *Abies*.

**The geographic distribution of deciduous and coniferous trees**, GRANER (*Jahresheft. Ver. Naturkunde Württemberg*, 53 (1897), pp. 142-179; *abs. in Bot. Centbl.*, 72 (1897), No. 2, pp. 305-308).

**Contributions to the knowledge of North American conifers**, E. BASTIN and H. TRIMBLE (*Amer. Jour. Pharm.*, 69 (1897), No. 7).—Treats of *Tsuga mertensiana* and *T. caroliniana*.

**The old field pine in New Jersey**, A. HOLLICK (*Forester*, 3 (1897), No. 12, p. 136).—Notes the occurrence of *Pinus taeda* in New Jersey.

**On the southern range of Lawson's cypress**, J. B. DAVY (*Erythea*, 5 (1897), No. 9, p. 99).—Notes are given on the southern range of *Chamaecyparis lawsoniana*.

**The Shasta fir**, F. V. COVILLE (*Gard. and Forest*, 10 (1897), No. 514, pp. 516, 517).—Notes are given on *Abies shastensis* and allied species.

**The weeping silver fir**, A. D. WEBSTER (*Gard. Chron.*, 3. ser., 22 (1897), No. 567, p. 324).

**Foreign evergreens adapted to Swedish parks**, C. J. ROSSANDER (*K. Landt. Akad. Handl. Tidskr.*, 36 (1897), No. 3, pp. 144-162).

**Evergreens in Alnarp park (Sweden)**, F. ULRIKSEN (*K. Landt. Akad. Handl. Tidskr.*, 36 (1897), No. 3, pp. 163-187).

**Sequoia gigantea**, G. MACKINLAY (*Gard. Chron.*, 3. ser., 22 (1897), No. 570, p. 379, fig. 1).—Illustrated notes are given of a sequoia tree that has been planted for 51 years in a park. The height of the tree at the time of writing was 74 ft. 3 in. and the circumference at ground level was 21 ft. 3 in.

**The fruit of Sequoia**, C. S. SARGENT (*Gard. and Forest*, 10 (1897), No. 514, p. 514, fig. 1).—The fruit of *Sequoia wellingtonia*, formerly *S. gigantea*, ripens in 2 years, while that of *S. sempervirens* ripens in 1 year.

**The weeping spruce** (*Gard. Chron.*, 3. ser., 22 (1897), No. 569, p. 368, fig. 1).—Figures and describes a rather remarkable form of *Picea excelsa*.

**Planting and thinning spruce woods** (*Gard. Chron.*, 3. ser., 22 (1897), No. 569, p. 360).

**The willow oak**, H. TRIMBLE (*Amer. Jour. Pharm.*, 69 (1897), No. 12, pp. 617-619).

**Recent investigations on forest injuries due to rust fungi**, H. KLEBAHN (*Forstl. Naturw. Ztschr.*, 6 (1897), No. 12, pp. 465-473).

**Recent legislation on State forestry commissions and forest reserves**, B. E. FERNOW (*U. S. Dept. Agr., Division of Forestry Circ.* 17, pp. 15).—Several States and Territories having enacted forest legislation since the publication of Circular 13 of this Division, the author has given a summary of the recently enacted laws of New York, Pennsylvania, Wisconsin, and Minnesota and the Federal legislation relating to the establishment of forest reservations.

### SEEDS—WEEDS.

**The vitality of seed treated with carbon bisulphid**, G. H. HICKS and J. C. DABNEY (*U. S. Dept. Agr., Division of Botany Circ.* 11, pp. 5).—The authors report upon a series of experiments conducted to test the effect of carbon bisulphid when used for the destruction of weevils and other insects in stored grain. Experiments were made on 35 varieties of grain and vegetables, 5 of cotton, 2 of peas, 3 of corn, 2 each of rice, garden beans, Kafir corn, barley, and wheat. The first series of experiments were conducted by placing the seed in an atmosphere saturated with carbon bisulphid. The seeds were allowed to remain for 48 hours, after which their germination was tested. The germinative ability of barley, rye, wheat, corn, crimson clover, millet, and rice was considerably decreased by the treatment. The others were practically uninjured. Other experiments were conducted in which the seed were treated for 24 hours and a limited experiment was conducted with grain in bulk.

In general it is stated that seeds of cotton, peas, beans, buckwheat, oats, cowpeas, and various members of the crucifers will withstand the most severe treatment without having their germination injured to any appreciable extent. On the other hand, corn, wheat, rye, and other seeds belonging to the grass family, with the exception of Kafir corn and oats, should be treated with caution, as excessive exposure to the gas seriously diminishes their vitality.

**On the germination of weeviled leguminous seed**, E. GAIN (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 3, pp. 195-197).—A report is made of more than 3,000 germinations, embracing seed of 31 species of leguminous plants, in which the author found considerable injury is done by the attack of the weevil. This injury is due to the following causes: (1) Destruction of part of the embryonic reserve; (2) mutilation of regenerative parts; (3) exosmosis, through which a very considerable quantity of the nutritive material in the seed is lost, and (4) the biological and mechanical action of the parasite. The injury due to the latter cause is not limited in its effect to the seed alone, but may be transmitted to the plant, resulting in a deteriorated growth.

**Three new weeds of the mustard family**, L. H. DEWEY (*U. S. Dept. Agr., Division of Botany Circ. 10, pp. 6, figs. 3.*)—Illustrated descriptive notes are given on 3 new plants of the mustard family which have been reported from several localities in northern United States and Canada during the past few years. Although confined to comparatively small areas and having thus far caused little damage, in some places they are becoming very aggressive weeds. The species enumerated are *Berteroa incana*, the hare's ear mustard (*Conringia orientalis*), and ball mustard (*Neslia paniculata*).

**Testing seeds**, C. D. WOODS (*Maine Sta. Bul. 36, pp. 8.*)—This bulletin contains "An act to regulate the sale of agricultural seeds," enacted by the Maine legislature, and rules for testing the purity of seeds taken from those adopted by the Association of American Agricultural Colleges and Experiment Stations, but modified to conform to the requirements of the law of the State. Standards of purity and germination of agricultural seeds are given in a table.

**Concerning the germination of Fraxinus**, G. F. L. SARAUW (*Tidsskr. Skov., 6, pp. 62-70.*)

**Concerning the longevity of seeds and their preservation in the soil**, NAUDIN (*Bul. Soc. Nat. Acclim. France, 1897, Feb.-June.*)

**The vitality of refrigerated seeds**, H. T. BROWN (*Nature, 57, No. 1468, p. 150.*)—Calls attention to the work of Giglioli on latent vitality of seeds (*E. S. R., 7, p. 406.*)

**Concerning the composition of the seed and etiolated seedlings of Lupinus angustifolius**, M. MERLIS (*Landw. Vers. Stat., 48 (1897), No. 6, pp. 419-454.*)

**Work with weeds**, B. D. HALSTED (*New Jersey Stat. Rpt. 1896, pp. 402-404, figs. 2.*)—A case for examining commercial seed for weed seed and other foreign matter is figured and described. The Russian thistle which was reported from Weehawken last year seems to have been destroyed, no trace of it being reported during the year, nor has it been found elsewhere in the State. The occurrence of dodder upon seedling eggplants grown in a hotbed and upon onions is reported.

**Cuscuta monogyna on grapes**, A. ROLLOFF (*Ztschr. Pflanzenkrank., 7 (1897), No. 4, p. 213.*)—The occurrence of this species of dodder on grapevines is mentioned, and placing finely cut straw thickly about the vines is recommended as a preventive means.

**On the eradication of Cuscuta**, NOFFRAY (*Jour. Soc. Agr. Brabant-Hainaut, 1897, No. 40.*)

**Noxious weeds** (*Jour. Agr. and Ind., South Australia, 1 (1897), No. 4, pp. 322-324, figs. 2.*)—Notes are given of the Canada thistle and of *Xanthium spinosum*.

**Effect of Swainsonia galegifolia on sheep**, C. T. MARTIN (*Agr. Gaz. New South Wales, 8 (1897), No. 6, pp. 363-369.*)

**Concerning Lathyrus tuberosus as a grain-field weed**, R. SCHÄFFER (*Jahresber. Prens. Bot. Ver., 1896-97, p. 45.*)

**Poisonous plants of Germany**, F. G. L. GRESSLER (*Langensalza: F. G. L. Gressler, 1897, pp. 40, pls. 8.*)

## DISEASES OF PLANTS.

**Report of the botanist**, B. D. HALSTED (*New Jersey Stat. Rpt. 1896, pp. 289-429, figs. 60.*)—The work of the botanical department of the station for the year was mostly field experiments at the college farm and elsewhere, supplemented with laboratory investigations. The principal lines of work were with fungicides on various truck crops and on a few kinds of ornamental plants. A study of the peach gall was

the principal investigation carried on in the greenhouse. Some horticultural work included in the report is noted elsewhere.

During the year the experimental plat for botanical work was increased to nearly 2 acres. Several hundred specimens were added to the herbarium during the season, and some attention was given to a study of weeds and the determination of foreign matter in commercial seeds.

*Experiments with turnips* (pp. 294-309).—After summarizing the experiments for the previous four crops the author reports upon the work done in 1896 for the prevention of club root. Of the various fungicides tried unslaked lime has thus far proved to be the only efficient treatment for the prevention of club root of cruciferous plants. It is recommended that it be applied at the rate of from 75 to 150 bu. per acre. This application should be made every other year on land badly infested with the fungus where cabbages, turnips, or allied plants are yearly grown.

Plat experiments indicate that the fungus of club root can remain active in the soil for at least 2 years, and from box experiments in which the soil was considered free from the fungus it was apparent that manure may be the means of carrying the infection to the soil.

The author tested 16 species of cruciferous plants to ascertain their susceptibility to club root. Those so tried were candytuft, sweet alyssum, wild sweet alyssum, shepherd's purse, rockcress, wormseed mustard, peppergrass, field peppergrass, stock, penny cress, radish, rocket, black mustard, charlock, white mustard, and false flax. Of these, stock alone was unaffected, while charlock proved most subject to attacks of the disease, followed closely by white mustard. The necessity of keeping these weeds out of fields is obvious. Radishes, rocket, sweet alyssum, and candytuft were least affected.

*Experiments with potatoes* (pp. 309-319).—In continuation of the experiments of previous years, reported in Bulletin 112 and the Annual Report of the station for 1895 (E. S. R., 7, p. 780; 8, p. 893), the prevention of potato scab was investigated. The author states that Bordeaux mixture and ammoniacal copper carbonate were efficient to some degree in controlling scab. Sulphur took the lead among the soil treatments, and its effect on the soil is claimed to be lasting. Treating seed with sulphur or corrosive sublimate, while efficient in clean soil, will not avail much in badly infested soil. A mixture of 300 lbs. each of sulphur and kainit per acre is recommended as a combined fungicide and fertilizer for use on scab infested lands.

An opportunity was offered to test the respective value of the bud and stem ends with the middle of the potato when used in planting, also the effect of depth of planting. The superiority of the middle portions over the end cuttings was established, so far as this experiment was concerned. It is claimed that planting more than 4 in. deep is not justified on account of greater labor.

Potatoes planted upon turnip land that had not been planted to potatoes for 6 years gave a larger total yield of tubers, but the crop was practically worthless on account of scab.

*Experiments with sweet potatoes* (pp. 319-328).—Experiments for the prevention of soil rot of sweet potatoes are reported in continuation of those given in the Annual Report of the station for 1895 (E. S. R., 8, p. 893). Lime, sulphur, manure, corrosive sublimate, kainit, and copper sulphate were tested singly and in different combinations, and as in the previous experiment sulphur gave the best results, followed closely by kainit and copper sulphate and kainit alone.

Additional experiments are reported on the cost and value of sulphur, when given field trials, as a preventive of soil rot.

A brief illustrated description is given of the stem rot of sweet potatoes, but no treatment is suggested.

*Experiments with beans* (pp. 328-333).—Investigations have been continued on the anthracnose and bacterial disease of beans. Anthracnose was nearly checked by spraying the plants and the occurrence of the bacterial disease was greatly diminished on the sprayed plants.

The author states that experiments with beans to determine the effect of depth of planting indicate that between 1 and 2 in. is probably the best depth for the variety used (Golden Wax).

*Experiments with tomatoes* (pp. 333-336).—Tomatoes were grown for 3 years on the same soil. The amount of leaf blight (*Septoria lycopersici* and *Cladosporium fulvum*) increased with each succeeding crop, while the fruit rot (*Glaosporium phomoides*) was about the same for each crop. This seems to indicate that there is some connection between the old tomato plants allowed to remain on the ground and the diseased condition of the succeeding crop. The fungicides tested were equally efficient in preventing leaf blight. Irrigation for tomatoes gave negative results this year.

*Experiments with peppers* (pp. 336, 337).—Experiments designed to test the value of fungicides for the prevention of the fruit anthracnose gave negative results, all being apparently without effect.

*Experiments with eggplants* (pp. 337-340).—In continuation of the experiments reported in the Annual Report of the station for 1895 (E. S. R., 8, p. 894) the diseases of eggplants were investigated. The season was very favorable for the development of fungi, and on both sprayed and unsprayed plants only about a third of the fruits were marketable.

A stem disease appeared that did not seem to be affected by any of the fungicides used. As shown in the previous report, Bordeaux mixture reduced the amount of disease where the plants were grown on fresh soil. The growing of 2 successive crops of eggplants on the same soil is believed inadvisable.

*Experiments with cucumbers* (pp. 340-344).—After summarizing the results of his previous year's work (E. S. R., 8, p. 395) the author gives

an account of the experiments conducted in 1896 for the prevention of mildew and anthracnose of cucumbers. Owing to the early destruction of the vines by insects the results are hardly conclusive. The fungicides seemed to act to some degree as repellants toward the insects, as the sprayed vines were the last to be destroyed. The leaf blight was prevented to a considerable degree by the fungicides used. The fruit rot was about 5 per cent worse on the plants which were sprayed with the potash solution.

*Experiments with celery* (pp. 344, 345).—Negative results are reported on the use of fungicides for the prevention of celery blight, there being no disease manifest on any of the plants.

*Experiments with peas* (pp. 345, 346).—Investigations were conducted for the prevention of the leaf blight (*Ascochyta pisi*) and mildew (*Erysiphe martii*) on peas. A quick-growing variety, First of All, was chosen for the trial, the object being to get several successive crops in one season. No apparent effect from blight was found in the first crop. Irrigation materially increased the yield of vines and pods. In the second crop old seed and new seed from the crop just harvested were planted to the evident advantage of the new seed. Soil treatments of sulphur, corrosive sublimate, carbonate of lime, and copper sulphate were tested with the expectation that they would check the disease coming on the stems near the ground. The best yields were secured where the carbonate of lime was employed. But very slight differences were observed in the amounts of blight on the different plats. On the third crop the effect of Bordeaux mixture in keeping off the diseases from late peas was very evident.

*Experiments with beets* (pp. 346-350).—Experiments were conducted for the prevention of some of the fungus attacks of beets, principally *Cercospora beticola*, which was described in Bulletin 107 of the station (E. S. R., 6, p. 905). The fungicides were efficient in increasing the yield of the treated plats, although the ammonia-Bordeaux mixture burned the foliage to a considerable degree.

The identity of the scab upon potatoes and beets was clearly established by a field inoculation.

*Experiments with sunflowers* (pp. 350, 351).—A test was made of fungicides for the prevention of attacks of *Puccinia tanacetii* on sunflowers. Twelve sprayings were given the plats, and it was found that all the fungicides were active in keeping down the fungus. Those plants receiving what was called the ammonia-Bordeaux mixture were almost entirely free from rust pustules.

A stem blight due to *Phlyctena* sp. was noticed on some of the plants and it did not seem to yield to applications of fungicides. An allied species of this fungus has been reported on cosmos.

*Experiments with onions* (p. 352).—Tests were made in the greenhouse with sulphur and corrosive sublimate for the prevention of onion smut due to *Urocystis cepulae*, but no disease appearing in either check or treated lots, the results were negative.

*Experiments with corn smut* (p. 352).—Negative results similar to the above were obtained from experiments on the prevention of smut carried on in the greenhouse.

*Fungicides and spraying* (pp. 352–378).—Formulas for the fungicides used in the above experiments, details of application, and notes on their behavior toward the different plants are given. The principal fungicides employed were Bordeaux mixture and 3 modified solutions in which the lime of the Bordeaux mixture was replaced by soda, potash, and ammonia. The experiments above mentioned with lime, corrosive sublimate, kainit, copper sulphate, sulphur, etc., are reviewed.

*Experiments with ornamental and other plants* (pp. 396–400, 405–413).—Experiments are briefly reported on attempts to combat blight of peonies, leaf spot (*Cercospora cereidicola*) of Japanese redbud, leaf blight of hollyhock due to *Cercospora althaina*, diseases of gladiolus, prevention of rust of china asters caused by attacks of *Coleosporium sonchiarrensensis* (?), and experiments with sweet peas and stem blight (*Phlyctena* sp.) of cosmos. Experiments reported with water lily blight indicate that Bordeaux mixture will prevent the disease, although the incrustation on the leaves is objected to.

The rust of asparagus is reported upon at considerable length. The fungus *Puccinia asparagi* seems to be spread along the Atlantic coast from Virginia northward. All varieties seem equally susceptible except the Palmetto. This seems thus far to be partially resistant. Burning the dead tops in the fall is recommended.

Notes are given on a nasturtium blight, an ampelopsis blight, an anthracnose of magnolia, a blight of chestnut, and a blight of linden.

*Experiments with peach root galls* (pp. 413, 414).—The application of sulphur about the roots of the seedlings seemed to indicate that it could be relied upon for the prevention of the root galls. There appears to be no connection between the cause of the galls on the peach roots and those on raspberry roots.

*Siftings from other sources* (pp. 415–429).—Under this heading are given abstracts of various publications of the stations and of this Department.

**Bacteriosis of carnations**, A. F. WOODS (*Bot. Gaz.*, 24 (1897), No. 3, pp. 200–205).—The author has investigated the diseases of carnations described by Arthur and Bolley<sup>1</sup> as baeteriosis of carnations. He concludes that the disease is not due to bacteria, as has been supposed, but to the punctures of aphides and thrips. The cells affected become œdemic, collapse, and give a whitish sunken area. In the early stages no bacteria or fungi are associated with the disease, though the dead tissue may be infected later. Proper selection and propagation of stock and keeping down as far as possible the aphides and thrips are recommended as measures for preventing the disease.

<sup>1</sup> Indiana Sta. Bul. 59 (E. S. R., 8, p. 235).

**The Bermuda lily disease**, A. F. WOODS (*U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Bul. 11, pp. 15, figs. 4*).—A preliminary report is given of investigations conducted to ascertain the causes and means of prevention of the lily disease. This disease is characterized by the spotting and distortion of the leaves and flowers and usually the stunting of the plant, and it quite seriously affects the varieties of *Lilium longiflorum* and *L. harrisii* and also attacks *L. auratum* and *L. candidum*. The disease is said to be very prevalent in Bermuda and in the United States, where it frequently destroys 20 to 60 per cent of the crop.

The principal causes of the disease are said to be worn-out soil, premature removal of flowers and flower stems, premature harvesting of the bulbs, carelessness in the selection of stock for propagating purposes, bad treatment during forcing, and the work of insects. The investigations of the author seem to indicate that the disease is due to a combination of these causes. Bulbs become weakened through improper selection and propagation, and this weakening is further increased by attacks of mites and certain fungi and bacteria. During the forcing of the plants the bulbs may be weakened by overwatering or by allowing the roots to become too dry and then overwatering, the leaves of such plants usually being badly diseased. The spotting and distortion of the foliage is often due to the direct attack of several species of aphides and the young of the bulb mite, the injection of water into the leaves in watering by syringing, and the presence of water between the leaves of plants having soft foliage.

The means suggested for prevention of the disease are necessarily numerous. Among those apparently most important are proper cultivation, selection, and propagation so as to improve the stock; crop rotations should be practiced in order to prevent the increase of mites and injurious fungi; the stems should be left on the bulbs to secure their proper ripening, and care should be used in planting. All injured bulbs should be thrown out and planting should be done in well-drained and well aerated soil. As far as possible attempts should be made to keep down injurious insects from the start, and great care should be exercised in watering and ventilating. Chemical fertilizers are recommended in place of barnyard or other manures.

**Sooty mold of the orange and its treatment**, H. J. WEBBER (*U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Bul. 13, pp. 44, pls. 5*).—This bulletin is in continuation of investigations given in Circular 15 and Bulletin 8 of this Division (*E. S. R., 6, p. 737; 8, p. 59*). In the present bulletin the author has given rather extendedly the life history of the fungi (*Meliola penzigi* and *M. camelliae*) causing the disease. The sooty mold is considered a saprophytic fungus, deriving its nourishment wholly from the honeydew secreted by various insect pests which the fungus invariably follows. The most important of these insects is the mealy wing or white fly (*Aleyrodes citri*). In

experiments with various sprays and washes resin wash, resin compound, an emulsion of pyrethrum and kerosene, and a resin wash containing a tobacco decoction proved very effective. Fumigation with hydrocyanic acid gas has also given excellent results. The treatment for sooty mold should be made during winter, in May, and in August or the early part of September. The trees should be given 2 or 3 sprayings during the winter and 1 in May, another application being made during August if the fungus is found to be spreading to the fruit.

Several entomogenous fungi have been discovered which will probably greatly aid in holding in check the sooty mold and the pests which it follows. The first of these (*Aschersonia aleyrodix*, n. sp.) is parasitic on the larvæ and pupæ of the mealy wing, and has been found very abundant in many groves infested with sooty molds. Only the larvæ and pupæ are subject to attack, infection taking place most commonly in the young larvæ. The fungus is fully described and its life history well worked out. A second fungus parasite, to which the name "brown fungus of the mealy wing" has been given, gives evidence of being more effective in its attack than the previous one. The relationships of the fungus can not be given, no fruiting bodies having been found. In the grove where this fungus was first discovered its spread was so rapid during the summer that the mealy wing was almost wholly eradicated.

Notes are given of other fungi which attack scale insects on several other plants.

**A seedling disease of cacti** (*Monatsschr. Kakteenkunde*, 7 (1897), No. 12, p. 188).—A brief note is given of a disease of cactus seedlings. Examinations of material revealed the presence of a sterile mycelium that is thought to be the cause of the disease.

**A disease of the mammoth tree of California** (*Meehan's Mo.*, 7 (1897), No. 12, p. 230).—A note is given of *Cercospora sequoia*, which is said to seriously interfere with the growth of *Sequoia gigantea* in the eastern States.

**A new disease of cauliflowers** (*Jour. Agr. and Ind., South Australia*, 1 (1897), No. 4, p. 343).—A brief note is given of a disease of roots of cauliflowers, due to a species of *Phoma*.

**A disease of clematis**, P. SORAUER (*Ztschr. Pflanzenkrank.*, 7 (1897), No. 4, pp. 255, 256).—A brief note is given of a disease of *Clematis jackmanni*, which is caused by *Glaosporium clematidis*.

**A sclerotium disease of tulip bulbs**, F. LUDWIG (*Deut. Bot. Monatsschr.*, 15 (1897), No. 5, pp. 153, 154).

**A new leaf disease of coffee in East Africa**, P. HENNINGS (*Ztschr. Trop. Landw.*, 1 (1897), No. 8, pp. 192, 193).—Describes *Hemileia woodii*.

**The diseases of fruit trees**, C. BACH (*Wehnbl. Landw. Ver. Badeu*, 1897, p. 84).

**The gummy deposits in the sereh disease of sugar cane**, A. WIELER (*Beitr. Wiss. Bot.*, 2. Abt., 1 (1897), pp. 29-140, pl. 1, figs. 23).

**New fungi parasitic on cultivated plants**, G. POLLACCI (*Atti Inst. Bot. Univ. Paria*, 2. ser., vol. 5, pp. 8; abs. in *Bot. Centbl.*, 72 (1897), No. 5, pp. 184, 185).—The following new species are described: *Macrosporium viola*, *Helminthosporium iberidis*, *H. lunariae*, *Leptothyrium parasiticum*, *Cytoporella cerei*, *Pirostoma farnetianum*, and *Phyllosticta dammaræ*.

Recent investigations concerning the cause of potato rot, FRANK (*Ztschr. Spir-itusind.*, 1897, *Ergänzungsheft 2*, pp. 7-9).

The destruction of barley by a new fungus parasite, FRANK (*Wchenschr. Brau.*, 14 (1897), No. 42, pp. 518-520).

The enemies of our gardens, L. LAFOREST (*Les ennemis de nos jardins*. Abberille: Paillart, 1897, pp. 318, ill.).

The barberry as a carrier and distributor of grain rusts, J. ERIKSSON (*Landw. Vers. Stat.*, 49 (1897), No. 1-2, pp. 83-95).—The author reviews the literature relating to this subject and shows that the barberry is a host plant for some phases of rusts, and on this account the destruction of all bushes in cereal-growing regions is advised. Directions for their eradication and control are given.

On the characteristics of the brown rust of wheat, J. ERIKSSON (*K. Landt. Akad. Handl. Tidskr.*, 36 (1897), No. 3, pp. 137-143).

## ENTOMOLOGY.

Proceedings of the eighth annual meeting of the Association of Economic Entomologists (*U. S. Dept. Agr., Division of Entomology Bul.* 6, n. ser., pp. 100, figs. 5).—At this meeting, held in Buffalo, New York, August 21 and 22, 1896, the following papers were read:

*The evolution of economic entomology*, C. H. Fernald (pp. 5-12).—The history of the subject is briefly traced from the earliest times to the present. In speaking of the future development of the subject, it is shown that the assistance of the chemist and the physiologist will be needed.

*Sometemperatureeffects on household insects*, L. O. Howard (pp. 13-17).—From temperature experiments performed to learn the degree of temperature that will prevent the ravages of the common clothes moth (*Tinea biselliella*), the black carpet beetle (*Attagenus piceus*), the leather beetle (*Dermestes rufpinus*), the dark meal moth (*Tenebrio obscurus*), and the cabinet beetle (*Trogoderma tarsale*), it was found that during summer months a temperature of 40 to 42° F. is sufficiently low for the purpose indicated.

*A three years' study of an outbreak of the chinch bug in Ohio*, F. M. Webster (pp. 18-25, maps 4).—This is the same as Ohio Station Bulletin 77 (*E. S. R.*, 9, p. 67).

*A new insecticide*, A. H. Kirkland (pp. 27-29).—It was found by the author that arsenic in soluble form transfuses the cells of plants and

plasmolyzes the protoplasm, and that this plasmolysis is in direct ratio to the solubility and quantity of the compound employed. The burning point of barium arsenate is stated to be reached when it is used at the rate of 20 lbs. to 150 gal. water; that is, upon oak and apple. Larvæ in the second, third, and fourth molt, it is stated, are killed within 5 days when sprayed with this compound in the proportion of 3, 4, and 5 lbs. to 100 gal. water: while larvæ in the fifth molt require 10 to 20 lbs.

The barium arsenate is obtained by precipitating arsenate of soda with a soluble barium salt, such as barium chlorid.

*Comparative tests with new and old arsenicals on foliage and with larvæ, C. L. Marlatt* (pp. 30-35).—Paris green, pulverized Paris green, Scheele's green, London purple, and arsenite of lead, both with and without an admixture of lime were employed. The first 3 were used in strengths of 1:160; 1:100; 1:80; and 1:53 $\frac{1}{3}$ . The London purple and a mixture of equal parts of Scheele's green and arsenite of lead were employed at the rate of 1:160 and 1:100. No injury resulted. But in another series of tests made on peach, apple, and cherry, in which the poisons were used at the rate of 1:100, some damage was done, as shown by the following table:

*Injurious effects of Paris green, Scheele's green, and London purple.*

Poison.	Peach.	Apple.	Cherry.	Cotton.
Paris green, ordinary ..	$\frac{1}{2}$ leaves lost ..	Very slight spotting.	No injury.....	No injury whatever.
Paris green, pulverized.	$\frac{3}{4}$ leaves lost ..	All more or less spotted.	Injury slight—insignificant.	Do.
Scheele's green .....	$\frac{5}{8}$ leaves lost ..	do .....	do .....	Do.
London purple.....	All leaves lost.	Much scalded, including edges.	do .....	Do.

The effect of arsenicals seems to be to hasten the ripening of the leaves and perhaps also of the fruit.

In experiments on larvæ, no noticeable difference between the poisons was found when used at the rate of 1:80. Used at the rate of 1:160, they gave somewhat unsatisfactory results. When used at the rate of 1:100, Paris green and Scheele's green show but little difference, either when used alone or with lime. London purple and arsenite of lead are much slower in their action.

The number of grains of active poisonous principle held in solution in each gallon of mixture when the latter is made in the proportion of 1:100 is stated to be as follows: Ordinary Paris green, 0.87; pulverized Paris green, 1.18; Scheele's green, 2.50; London purple, 7.93; arsenite of lead, 0.94.

Summarizing all his experiments, the author states that Scheele's green and arsenite of lead are to be preferred to any of the others.

*On the futility of trunk and crown washing against the elm leaf beetle, L. O. Howard* (pp. 36-38).—It is concluded that fully 70 per cent of the insects drop from the limbs and that this demonstrates the superiority of spraying over other methods of combating this insect.

*Insecticide soaps, C. L. Marlatt* (pp. 38-41).—Some 18 soaps were tested to learn whether when dissolved at the rate of 2 gal. water to 1 lb. soap they would remain liquid. Nine remained liquid even when placed in refrigerators at a low temperature, while the rest remained solid even at summer temperatures. The percentage of water contained in soaps was found to have nothing to do with their remaining liquid. It was also learned that the kind of lye employed is immaterial. Fish oil or other oily soaps are thought best.

*Scale insects and their enemies in California, J. B. Smith* (pp. 46-48).—An abstract of the author's report in the Annual Report of the New Jersey Experiment Station for 1896.

*Notes on some of the insects of the year in the State of New York, J. A. Lintner* (pp. 54-61).—A somewhat unusual absence of the attacks of several common pests is noted. Some of the insects mentioned are *Vanessa atalanta*, *Leucania unipuncta*, *Anisopteryx vernata*, *Cacæcia rosaceana*, *Nolophana malana*, *Euphoria inda*, *Elaphidion villosum*, *E. parallelum*, *Crioceris asparagi*, *Macrobasis unicolor*, *Aspidiotus perniciosus*, *Kermes galliformis*, and *Gossyparia ulmi*.

*Entomological notes from Maryland, W. G. Johnson* (pp. 63-66).—The nursery stock law of Maryland is discussed. The recognized impossibility for even the expert to be certain that scales have been exterminated impels the author to suggest that a certificate should be required from nurserymen stating that their stock has never been infected or subject to infection and that they will assume all responsibility should their belief prove unfounded.

The following insects are noted: *Crioceris asparagi*, the potato stalk weevil (*Trichobaris trinotata*), *Doryphora 10-lineata*, *Epicauta cinerea*, the strawberry weevil (*Anthonomus signatus*), the plum curculio (*Conotrachelus nenuphar*), codling moth (*Carpocapsa pomonella*), fruit bark beetle (*Scolytus rugulosus*), European elm leaf beetle (*Galerucella luteola*), and a locust leaf beetle (*Odontota dorsalis*).

*Insects of the year in Ohio, F. M. Webster* (pp. 66-71).—This was reprinted in the author's annual report (E. S. R., 8, p. 998). In the discussion that followed a probably new apple trypet and a possibly new bagworm were noted, and the injurious effect of surrounding trees with cotton bands saturated with oil brought out.

*Some notes on observations in West Virginia on farm, garden, and fruit insects, A. D. Hopkins* (pp. 71-74).—The 5 localities in the State where the San José scale occurs are mentioned and the following insects noted: The scurfy bark louse (*Chionaspis furfurus*), the rose scale, the plum scale, webworm, the harlequin cabbage bug, blister beetle (*Epicauta pennsylvanica*), and a clover seed pest (*Bruchophagus (Eurytoma) funebris*) formerly thought to be parasitic on the clover midge (*Cecidomyia leguminicola*), and bumblebees.

*Notes on new and old scale insects, W. G. Johnson*, (pp. 75-78).—The insects noted are the cherry scale (*Aspidiotus forbesi*), *A. urv*, *A. ulmi*,

*A. asculi*, *A. aurantii*, *A. camelliae*, *A. ancylus*, *A. nerii*, *A. juglans-regiae*, *Mytilaspis pomorum*, *Chionaspis furfurus*, *C. salicis*, *C. pinifoliae*, *Diaspis rosa*, *Lecanium persicae*, *Prospalta murtfeldti*, *P. aurantii*, *Perrisopterus pulchellus*, *Signiphora nigrita*, *Arrhenophagus chionaspidis*, *Ablerus elisio-campa*, and *Chilocorus birulnerus*.

*Notes on the entomological events in 1896 in Ohio, H. Osborne* (pp. 78-80).—The army worm did considerable damage as a first brood; the second, which appeared in July, threatened injury, but was severely attacked by *Microgaster militaris*. The other insects noted are a leaf hopper (*Empoa albipicta*), an enemy of potatoes, *Aspidiotus rosa*, the hickory bark beetle (*Scolytus 4-spinosus*), the Hessian fly (*Cecidomyia destructor*) which was accompanied by its parasite (*Semiotellus destructor*), and the elm span worm (*Eugonia subsignaria*), which is said to have defoliated large tracts of timber land.

*Is cooperation for the control of the San José scale practicable, W. G. Alwood*, (pp. 80-84).—After considering the numerous difficulties involved, it is concluded that it would be impracticable to enact a general law by the different States affected with the scale and that the matter should be taken up by the General Government. The great need of systematic inspection and treatment of infected stock is brought out.

*The development of the Mediterranean flour moth, F. H. Chittenden* (pp. 85-88).—The life cycle was found to vary from 38 to 114 days, the usual length of time necessary being from 38 to 52 days. The egg state lasts from 4½ days to as long as 2 weeks. The pupal period lasts from 8 to 27 days and the larval period from 24 to 25 days.

*A grasshopper disease in Colorado, C. P. Gillett* (pp. 88-92).—Grasshoppers were found attacked by a bacterium resembling *Bacterium termo*. It was found that *termo* from beef broth sprayed on alfalfa and fed to healthy hoppers had the same effect as the germs from the insects, killing them within 48 hours; and when inoculated directly into the body, killing within 24 hours. The disease was found to spread readily and over a large extent of country. Soon after some of the experiments were performed in which dead and diseased hoppers were mixed with water and sprayed on the food plants dead hoppers were found over a mile away. The rearing of *Sarcophaga cimbisis*, *S. sarraceniae*, *S. sp.*, *Cyrtoneura stabulans*, *Helicobia heliceis*, *Apharecta musca*, and *Perilampus sp.*, is noted. The bacterial disease is said to be most prevalent in a wet time and upon low ground, and is confined mostly to 2 species, *Melanoplus bivittatus* and *M. femur-rubrum*. It is thought to be present in most localities in the State, at least to a small extent.

*A simple device for the preparation of oil emulsions, H. A. Morgan* (pp. 93, 94, fig. 1).—A 4-inch tin cylinder, from 20 to 24 in. long, provided with 7 small openings and a plunger, consisting of a tin cone and a ¾-in. iron rod, is described.

Following this paper is the constitution and by-laws of the association and a list of the members.

**Report of the entomologist, J. B. SMITH** (*New Jersey Stas. Rpt. 1896, pp. 433-563, figs. 16*).—This voluminous report is devoted largely to a consideration of the San José scale in California and other parts of the United States, with especial reference to the best means of dealing with it in New Jersey. There is besides this a discussion of the insects most injurious during the year in New Jersey. Among these the army worm is mentioned as having appeared in very destructive numbers in various parts of the State. This insect is described in detail, its life history, natural enemies, and the proper remedial measures are discussed. From several places it was reported as attacking oats, wheat, rye, grass, and corn. Its distribution was somewhat irregular and, as a whole, comparatively little injury was done, it being confined in some cases to single fields. In no place did it appear as a second brood.

The number of worms is controlled by climatic conditions that favor the development of disease and by natural enemies such as *Calosoma calidum* and the fly, *Nemorea leucania*. The most practical remedy, the author thinks, is poisoned bran, but if this is unavailable the furrow barrier remedy may be resorted to, or, if the insects are in a small area, kerosene may be used. In any case remedial measures should be taken early.

Other insects noted in the general review as injurious during the year are the melon louse, which caused considerable financial loss; the Hessian fly, strawberry leaf roller, root lice, strawberry weevil, cut-worms, wireworms, currant spanworm, and the caterpillars of the cabbage butterfly; the last were exceptionally numerous. There was scarcely a field in some portions of the State which was not seriously injured.

Injuries were also done by the oak pruner, hay worm, pear midge, pine sawfly (*Lophyrus abbotii*), vine leaf hopper (*Erythronoeura vitis*), maple pseudococcus (*Pseudococcus aceris*), tulip soft scale (*Lecanium tulipifera*), click beetle (*Monocrepidius respertinus*), locust leaf beetle (*Odontota dorsalis*), and the harlequin cabbage bug (*Murgantia histrionica*). The last insect, it is stated, has hitherto not been injurious in New Jersey. The reports of its ravages were first received from Camden.

Discussing the subject of sprays it is noted that a spray made of 1 lb. arsenic to 200 gal. of water will be perfectly safe and effective in the case of currants if applied 2 weeks before picking time. Hellebore, ordinarily effective against the currant worm, was tried against the spanworm with little success.

The author's experience with Dendrolene during the year was much the same as in the previous season. Applied thick and allowed to remain on thin barked trees it causes injury. Since chemical tests show that it is neither acid nor alkali and is not poisonous, the injury is thought to be due to the penetration of the greasy substance into the plant cells.

The results of correspondence relative to the common injurious

insects, some of which have already been named, are briefly summarized:

In his historical review of investigations on the San José or pernicious scale (*Aspidiotus perniciosus*) the author states that probably the insect was introduced into South America (its supposed original home) on trees from California, for it has not yet been found there on native plants. It has been supposed to have originated from Australia, the Pacific islands, and Japan, but no known facts justify a definite statement as to its originating in any of these places.

The history of the scale in the United States is briefly discussed, and its introduction into New Jersey is treated at some length. On the recommendation of the State board of agriculture the State legislature in 1896 appropriated \$1,000 for studying the scale. The author made a trip through the Southwest, California, and into Oregon to study the scale, and an account of this journey is given. The accounts of various people in California were very conflicting, with the exception of those relating to the usefulness of *Vedalia cardinalis*, which is stated to have almost exterminated the cotton cushion scale (*Icerya purchasi*). In Santa Barbara olive orchards once badly infested with the black scale were found among the cleanest seen, and this difference in condition was said to be due to coccinellids entirely. Of these *Rhizobius ventralis* was claimed to be most active. At Los Angeles the twice stabbed ladybird (*Chilocorus biculnerus*) is chiefly relied upon in combating the pernicious scale. At other places no dependence whatever was placed upon predaceous insects, but a resinous spray was used as a remedy. In other localities sprays were in disrepute.

Relative to *Rhizobius* the author states that *R. debilis* plays the most important rôle in the destruction of the scale, and that this species is found abundantly only in Santa Barbara County. What was called *R. debilis* elsewhere was found upon investigation to be *R. lophantæ* or *Scymnus marginicollis*.

Resummarizing his discussion and bringing out the question of the desirability of introducing predaceous insects into New Jersey, the author says, in substance, that the conditions in California can not be duplicated in New Jersey. South of San Francisco some six or eight weeks before the scale begins to reproduce it is preyed upon by *Chilocorus biculnerus* and *Aphelinus fuscipennis*. In some places these insects may feed upon it during its entire dormant period. When the scale is most sluggish and reproducing slowly (during the hottest season) *Rhizobius lophantæ* is most active. In New Jersey *C. biculnerus* and *A. fuscipennis* are native. *R. lophantæ* might be introduced, but it would be at a disadvantage, since it would not get as early a start as in California, nor would it be favored by a decreased activity of the scale.

Further, the scale has in New Jersey the advantage over all its enemies by breeding a month longer than they do. Another reason

unfavorable to the introduction of the beetle is that clean culture is more or less inimical to it.

In California where orchards were practically abandoned and became filled with rubbish the beetles flourished, finding sufficient shelter for the mild winters. In New Jersey, a much colder climate, much greater shelter would be necessary, and in its well-cultivated orchards very little would be found. Especially would this be the case in orchards of deciduous trees. From these facts the author concludes that even if the beetles should be introduced from California, and should do just as well as they have done there, the New Jersey orchardists would not be justified in relying on them to prevent or lessen the ravages of the San José scale. In southern California climatic influences, combined with the attacks of the natural enemies, keep the scale in check. The natural enemies alone could not do so, and any dependence upon them in New Jersey will, in the opinion of the author, result in disaster. If anything is done example must be taken from northern California, where the natural conditions much more nearly resemble those of New Jersey.

The remainder of the report is devoted to discussing (1) the relation of injurious insects to their enemies, and (2) the natural enemies of the San José scale, under which heads the author contradicts the quite popular idea that one may array the forces of nature against one another with entire success.

It is believed that natural enemies of the scale could not be introduced from California into New Jersey with a good prospect of their becoming sufficiently abundant within a measurably short time to be of much use in keeping the scale in check. The diseases of the scale are briefly treated, and a record is given of the insects introduced into New Jersey as a result of the author's western journey.

With reference to remedial measures, receipts are given for the lime, sulphur and salt wash, and for resin washes; the methods of using kerosene soaps and potassium cyanid are described; and the following recommendations are made:

"(1) Destroy infested stock whenever practicable; (2) spray thoroughly as soon after the trees become dormant as possible, with fish-oil soap, 1 lb. in 1 gal. of water; (3) spray again in early spring, before the buds begin to swell, with fish-oil soap, 2 lbs. in 1 gal. of water, and do it thoroughly; (4) cut back or prune the treated trees a few days after spraying, so as to leave no more wood than absolutely necessary for the use of the tree and crop; and (5) on scaly trees use whitewash liberally throughout the summer, keeping the trunks and branches covered with lime as thoroughly as possible."

**Some miscellaneous results of the work of the Division of Entomology**, L. O. HOWARD (*U. S. Dept. Agr., Division of Entomology Bul. 7, n. ser., pp. 87, figs. 44*).—This publication is designed in a measure to take the place of *Insect Life* and includes the following articles:

*The ambrosia beetles of the United States*, H. G. Hubbard (pp. 9-30).—A popular summary of what is known concerning various species of

ambrosia (*Platypus*, *Nyleborus*, *Corthylus*, *Monarthrum*, *Xyloterus*, and *Gnathotrichus*), found in the United States.

*Grasshopper report for 1895, L. Bruner* (pp. 31-35).—A brief account of an excursion into Colorado and the Northwest to investigate the locust conditions of those regions. In the neighborhood of Denver, Golden, and Fort Collins the most abundant insects observed were *Melanoplus bivittatus*, *M. atlantis*, *M. fædus*, *M. packardi*, and *Dissosteira longipennis*. The damages caused by these locusts, though comparatively light, were sufficient to warrant the settlers in taking decisive action. Numbers of the insects were attacked by *Empusa grylla*. To the heavy rains which were followed by a rank growth of vegetation the author attributes the bunching and the eastward and northward spread of the long-winged species. Between Cheyenne, Wyoming, and Oreno Junction, Wyoming, where the hoppers had been particularly numerous in previous years, few were found, in consequence, apparently, of a series of cold rains during the months of May and June. Near Laramie City *Camnula pellucida* was found very abundant in places, but the other species were not present in even moderate numbers. North of Ogden the most numerous species were *Melanoplus bivittatus* and *M. atlantis*. In some places *Camnula pellucida* was present in more than ordinary numbers. At Logan most of the commoner species were abnormally abundant. At Pocatello, Idaho, slight indications of locusts were noticed. Along the Snake River and thence to Colfax, Pullman, Moscow, Lewiston, and Waha, they were found to have done more or less injury and in many places were still active. Among the species observed were *Melanoplus femoratus*, *M. fædus*, *M. atlantis*, *Camnula pellucida*, and *Dissosteira obliterata*.

As a result of his observations the author concludes this year was one of unusual drought for this part of the country, and that, as the grass on the hillsides and in the pastures was shorter than usual and consequently sooner grazed off by the stock, the hoppers were forced to move to cultivated grounds; and, taking the region as a whole, considerable damage was done, although no single district may be said to have been completely devastated. The hoppers appear to be on the increase, but there is no apprehension of an invasion from the Rocky Mountain locust at any point, although there may, and probably will, be local outbreaks of native species.

*Grasshopper report for 1896, L. Bruner* (pp. 36-39).—This records a journey undertaken to investigate reports of grasshopper injuries in Nebraska, Dakota, Kansas, Minnesota, Iowa, and Colorado. Some of the early reports were found to be largely caused by *Melanoplus spretus*. Later reports from north of the Platte River were found to be caused by the long-winged plains locust, *Dissosteira longipennis*. Investigation showed the insects were not in such numbers as to cause great injury except in isolated districts. The other species found to be destructive in Nebraska and adjoining States were *Melanoplus atlantis*, *M. femur-rubrum*, *M. bivittatus*, *M. differentialis*, and *M. lakinus*. *M. atlantis* was

noted in portions of Colorado and Kansas and in the central half of Nebraska, western Iowa, and some parts of South Dakota and Minnesota as very plentiful. At Lincoln it showed a tendency to migrate during the month of September. In Colorado and western Kansas the hoppers were found to be attacked by *Empusa grylla* and consequently upon the decline. At Colorado Springs and vicinity *Melanoplus lakinus* seemed to be on the increase and to have apparently passed the danger line. *Dissosteira longipennis* was especially noted as having attacked cultivated plants not before included in its list of food plants. In the vicinity of Lodge Pole fields of small grain were destroyed by it; some corn, potatoes, and a number of garden plants were destroyed by it. In the vicinity of Sidney large numbers of a long-legged tachnid fly were found apparently attacking and destroying the locusts.

*Some insects affecting the hop plant*, L. O. Howard (pp. 40-51).—Brief notes on the hop plant borer (*Hydracia immanis* and *Hyppena humuli*), the semicolon butterfly (*Polygonia interrogationis*), and comma butterfly (*P. comma*).

*The plum plant louse (Myzus mahaleb)*, T. Pergande (pp. 52-59).—*Myzus* is to be distinguished from *Phorodon* by gibbous frontal tubercles and the absence of a tooth in the first antennal joint in the case of *Myzus* and by the tubercles being prolonged into a permanent slender prorected tooth and by the first antennal joint being bluntly but distinctly gibbous in the case of *Phorodon*. The food plants of various species and the life history of *M. mahaleb* are considered and the characteristics of the insect in each of its 3 different genera described in detail. The apterous females sometimes occur in the third generation, but differ from those of the second nearly as much as the second from the first generation. They are very similar and are to be considered a migratory form destitute of wings. Return migrants or pupiferous females are said to resemble closely those of previous generations, but they are generally larger and stouter and have all the markings more intensified. By the time the earliest sexual females are fully matured, which may be in about 3 or 4 weeks, the return migrants again become numerous and last until about December.

*The rose leaf beetle*, F. H. Chittenden (pp. 60-61).—The author notes that *Nodonota puncticollis* has been confounded with *N. tristis*, *N. elypealis*, and *N. convexa*. The different species may be identified by recollecting that *N. tristis* feeds on Lespedeza, Ceanothus, and other upland weeds; *N. elypealis* on ambrosia in river bottoms; *N. convexa* in the same situations, and *N. puncticollis* on wild and cultivated roses, blackberries, raspberries, strawberries, and red clover. He proposes to call this species the rose leaf beetle, since it seems to prefer that plant.

*A case of excessive parasitism*, L. O. Howard (pp. 62, 63).—The author describes a new species (*Coccephagus fletcheri*) and records that from 80 specimens of *Lecanium fletcheri* received on 4 little twigs of *Arbor vita*

from Ottawa, June 17, 1896, as many as 127 parasites emerged within 10 days. As the holes made by the emerging numbered 180 and as but a single parasite is known to emerge from one hole, many parasites must have emerged previous to the receipt of the specimens. This, in connection with other facts, indicates that the insects were parasitized to the extent of 97.5 per cent. Not a single hyperparasite was found among the 6 different species of 5 distinct genera of parasites that emerged.

*The walnut spanworm, D. W. Coquillett* (pp. 64-66).—Notes on the spanworm (*Boarmia plumigeraria*) which appeared late in the summer of 1890 in very considerable numbers in Santa Barbara County, California, upon the leaves of the English walnut. Previously it had not been known as an injurious insect. It has also been found upon the leaves of the apple, prune, and oak. The life history of the insect is given. A tachinid and an ichneumon of the genus *Apanteles* have been found parasitic upon the worms. Different birds, especially the black-birds, have been noted as particularly fond of them. The most efficient remedy is considered to be a spray of Paris green in the strength of 1 lb. of the poison to 200 gal. water. If to each 100 gal. of the solution 10 or 12 lbs. of soap are added, the efficacy of the solution will be increased and spraying facilitated.

*Insect injury to chestnut and pine trees in Virginia and neighboring States, F. H. Chittenden* (pp. 67-75).—The author treats here of the buprestid *Agrilus bilineatus*, and the scolytid bark beetle, *Dendroctonus frontalis*, which have been charged with killing chestnut trees, especially in the region southeast of the Blue Ridge Mountain range. Save in exceptional cases, perfectly healthy forest growths seldom succumb to insect attack and the cause of the injury must be sought in some predisposing agency producing a weakened condition of the timber. The primary cause of such injuries may be attributed to what is known as winter desiccation, or pine blight.

The author also describes the result of his visits to the infested regions. *Agrilus bilineatus* is briefly described and an undoubted parasite upon it (*Spathius simillimus*) noted. Complaints received from Virginia, West Virginia, and the District of Columbia that the pines were severely attacked were investigated and the damage found to be caused by *Dendroctonus frontalis*. *Leptostylus commixtus*, *Graphisurus pusillus*, and *Acanthocinus nodosus* were also found injuring pines.

The severe wind storms that occurred in the south Atlantic States during the year 1895 caused the destruction of forest and shade trees which then offered an excellent opportunity for the propagation of insects. To prevent still greater destruction of trees by these insects, the author states that those sufficiently interested should clear up the dead and trim the injured trees, and that all dead oaks ought to be burned. Besides this the plan followed in Europe might be adopted, which is to girdle certain trees here and there in the forest which form

trap trees which may later be cut down and burned. Raupenleim and Dendrolene might also be used upon the trunks and lower branches of shade trees for preventing the oviposition of eggs. A wash of lime poisoned with Paris green, rendered sticky by a little glue, might be used for the same purpose.

*General notes, L. O. Howard* (pp. 76-84).—Under this head *Gelechia piscipellis*, *Olliffiella cristicola*, the white pine butterfly (*Neophasia menapia*), the strawberry weevil (*Anthonomus signatus*), the scolytid (*Xyleborus tachygraphus*), the harlequin cabbage bug, meal worms (*Tenebrio obscurus*), the coccid (*Aonidia fusca*), the San José scale (*Aspidiotus perniciosus*), the common mealy bug of Europe (*Dactylopius adonidum*), and the apple insects (*Cacacia respersana* and *C. excessana*), are noted.

*Notes from correspondence* (pp. 84-87).—Miscellaneous notes including notes on the red winged starling (*Agelanus phoeniceus*), the cottonwood leaf miner, a migration of *Colias casonia*, the bollworm damage to strawberry plants, scolytid beetle (*Xyleborus pubescens*, *Monarthrum mali* and *M. fasciatum*), an unwelcome insect imported by the World's Fair, Oreodera in the West Indies, a new locality for *Bruchus obsoletus*, hippelates flies, early and new appearance of the horn fly, and a man-infesting bot (*Dermatobia cyaniventris*).

**The San José scale and its nearest allies**, T. D. A. COCKERELL (*U. S. Dept. Agr., Division of Entomology Bul. 6, tech. ser., pp. 31, figs. 15*).—The characteristics which distinguish these closely related injurious scale insects are considered. The characteristic features of scale insects belonging to the subfamily Diaspinæ and its genera are given and a key to a number of species of *Aspidiotus*.

It is noted that *A. cydonia* of Florida resembles *A. rapax*, and that the Mexican *A. crawii*, which is a fungus scale, is distinguished by the exuvie not being dark. *A. perniciosus* is recognized with difficulty in the field, since *A. ancyclus*, *A. forbesi*, and *A. howardi* closely resemble it. It is therefore recommended that a field diagnosis be confirmed by an examination of the insect beneath a compound microscope, if either locality or plant is new. *A. forbesi*, recently described from Illinois, is stated to have been found on apple trees in Mesilla, New Mexico.

The microscopic characters of the adult female, so far as of diagnostic value, are considered and figured with some detail.

The absence of ventral glands in immature females is noted as a diagnostic characteristic that is inconclusive. A close examination of the posterior marginal lobes in *A. perniciosus* will enable one to distinguish it from other forms. The median lobes are large, upright, and extero-marginally notched. The second lobes, though small, are distinctly set close to the first, varying slightly in shape, but inclining to be pointed, and like the other lobes are externally notched. The processes between the two lobes are well developed, close together, and of nearly equal size.

A comparison is made with the lobes of *A. ancyclus*, *howardi*, *ostreaformis*, *juglans-regiæ*, *albopunctatus*, *obscurus*, and *crawii*. The differences in the ventral glands are brought out in the following table:

Ventral glands of the species of *Aspidiotus*.

	Median.	Cephalo- laterals.	Caudo- laterals.
<i>A. perniciosus</i> .....	None.	None.	None.
<i>A. andromelas</i> .....	None.	None.	None.
<i>A. rapax</i> .....	None.	None.	None.
<i>A. juglans-regiæ</i> .....	0 to 4	7 to 16	4 to 8
<i>A. forbesi</i> .....	1 to 3	3 to 7	3 to 5
<i>A. ostreaformis</i> (from England) .....	6	11	9
<i>A. convexus</i> .....	None.	7	1
<i>A. ancyclus</i> .....	0 to 6	6 to 14	5 to 8
<i>A. cydoniæ</i> .....	None.	8 to 9	5 to 7
<i>A. crawii</i> .....	None.	5	4
<i>A. uvæ</i> (on grapevine) .....	0 to 2	4 to 9	3 to 8
<i>A. obscurus</i> .....	6	12	8
<i>A. howardi</i> .....	None.	6 to 7	3 to 4
<i>A. patavinus</i> (on cherry in Italy) .....	0 to 2	4 to 9	7 to 10

Comstock's division of the genus *Aspidiotus* into subgenera is commented upon and the various subgenera are considered at some length. *Melanaspis* (type *A. obscurus*), *Mycetaspis* (type *A. personatus*), *Pseudonidie* (type *A. duplex*), *Cryptophylaspis* (type *A. occultus*), *Selenaspis* (type *A. articulatus*), and *Xerophilaspis* (type *A. prosopidis*) are suggested as new subgenera.

The author endeavors to prove that the San José scale is a native of Japan, upon the ground that 2 varieties or subspecies of *A. perniciosus*, namely, *andromelas* and *albopunctatus*, occur in that country which agree almost exactly in structural details with *A. perniciosus*. The question of origin is discussed at considerable length. The older idea of the Chilean origin of *A. perniciosus*, as well as the Australian origin, is more or less summarily dismissed, and the observation made that the supposed variety of *A. perniciosus*, found by Maskell on Eucalyptus in Australia, is not correct. The species of *A. diaspidiotus* of the United States are not thought very closely related to those of Europe. The American species differ in the median lobes being nearer and more inclined to be notched. The author notes a tendency in the American species to give off a group with pallid and usually flatter scales, which are found in the peripheral parts of trees, leaves, and even fruit. By this means he draws *A. howardi* from *A. ancyclus*. *A. juglans-regiæ* is considered a very distinct form, suggesting in its scale *A. chrysomphalus*.

Under the head of habits of the species it is pointed out that *A. perniciosus* is partial to the Rosaceæ, as supported by the following list of host plants upon which it has been found: Apple, crab apple, quince, pear, Bartlett pear, dwarf Duchess pear, plum, Japan plum, Satsuma plum, *Prunus pissardi*, *P. maritima*, peach, apricot, almond, cherry, Rocky Mountain dwarf cherry, currant, black currant, *Citrus trifoliata* (*Albopunctatus*), osage orange, grape, elm, cottonwood, European linden, American chestnut, *Pyrus japonica*, *Catalpa bignonioides*,

walnut, Japan walnut, loquat, red dogwood, juneberry, rose, sumac, *Photinia glauca*, and the Carolina poplar.

An annotated list of the 134 species of *Aspidiotus* is given. In a postscript the author accepts Leonardi's new genus *Odonaspis* and drops a subgenus proposed by himself of which *A. secretus* was the type. He objects to the grouping of the species by Leonardi<sup>1</sup> which throws into the same genus (*Aonidiella*) such different forms as *A. aurantii*, *perniciosus*, and *mimosae*, while it places *perniciosus* and *uncylus* in separate genera.

**Distribution of the San José scale in Virginia,** W. B. ALWOOD (*Virginia Sta. Bul. 66, pp. 77-90, figs. 3*).—In May only 2 infected localities were known in the State, but as a result of personal inspection and correspondence since then the number of localities has been increased to 26, distributed through the entire State in 16 counties, including some 60 premises. Since the introduction of the pest into the orchard in Roanoke County 6 years ago it has increased so as to involve 10,000 trees in this county and 4,000 in the adjacent one of Botetourt. The distribution of the scale in the United States is also noted.

During the year all but a few small nurseries were inspected and were carefully watched. In this work the nurserymen of the State cooperated with the best of will. Where stock is known to be infested the author seems to advise its entire destruction and the treatment of only such stock as is suspected. Little faith is placed in washes for this latter purpose, fumigation being thought best.

For the purpose of fumigation of nursery stock, a two-roomed tight board building lined with paper and having a ground floor is described. The partition dividing the 2 rooms is tight, so that one room may be filled while fumigation is going on in the other.

**More about the San José scale,** C. F. BAKER (*Alabama College Sta. Bul. 86, pp. 151-156, figs. 2*).—The author states that the inspection of several nurseries in Alabama during the spring revealed the fact that this insect occurred but rarely or not at all on stock that was moved every 3 years, and he seems to advise such a movement of stock for the purpose of getting rid of the scale. The plan, it is stated on the authority of nurserymen consulted, is perfectly practicable.

Passing over a compiled list of the food plants of the insect, it may be noted that the Early Richmond cherry seems to be exempt from the San José scale. Trees of this variety have been growing with their branches interlocked with those of a pear that had been killed by the scale and yet remained uninfested. Again, two cases are noted where the Early Richmond variety was grafted upon Mahaleb stock. The shoots of the latter had sprung up below the graft and were badly infested, while none at all were to be found on the trees themselves.

<sup>1</sup>Riv. Pat. Veg., 5 (1897), No. 9-12, p. 283-286.

A brief description is given of the scale, and brief notes on a sweet-potato pest which some years ago was reported from Ocean Springs, Mississippi, as being injurious. A few notes are also given upon carbon bisulphid, insecticides, and pumps in general.

**The pear slug**, C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Circ. 26, 2. ser., pp. 7, figs. 4*).—The characteristics and the history of the insect are briefly reviewed. It is noted that a comparison of specimens from Europe with abundant American material establishes the fact that the American pear slug, which has been known under the names *Selandria cerasi* and *Eriocampa cerasi* and considered as an American insect, is identical with the *Tenthredo limacina* of Retzius<sup>1</sup> (1783) placed in the genus *Eriocampoides* by Konow in 1890.

The life history and habits are described from the egg stage to the adult. In the latitude of Washington the eggs are laid in April; in that of Boston during the latter part of May and the first of June. At Washington many of the newly hatched larvæ perish during the cold and wet weather that often characterizes April. Where a good many eggs are found on one leaf the author is convinced that it is by different flies, or at least at different visits of the same individual.

Relative to the pupa it is stated that the author's observations confirm those of Peck, viz, that some larvæ of the spring brood remain unchanged as dormant larvæ during winter and transform in the spring. At Washington, it is stated, nearly all of the first brood larvæ disappear about the end of June and the first flies of the second brood begin to appear about June 20—in greater number about July 1.

As a parasite a species of *Encyrtus* is noted. The usual arsenical remedies are recommended; e. g., Paris green at the rate of 1 lb. to 250 gal. of water. A soap wash and forcible water spraying are thought effective.

**The currant fly or gooseberry frit fly**, L. F. HARVEY (*Maine Sta. Bul. 35, pp. 8, figs. 10*).—A brief history is given of the insect *Epochra canadensis*. From a study of the life history of the insect, which as a pest is new to the State, it is concluded that it is vulnerable only in the larval stage. The larvæ remain in the fallen fruit for some time, and such fruit may therefore be gathered up and burned. A correspondent suggests that chickens might be allowed about the bushes with good effect. It is also suggested that the pupæ may be destroyed by deep spading or by stirring the soil after cold weather so as to expose the pupæ. Mulching is also recommended.

**Value of keeping bees on the ranch**, A. J. COOK (*Amer. Bee Jour., 37 (1897), No. 30, pp. 470-471*).—Among other things, the keeping of bees on a small scale by farmers and ranchers, rather than by specialists, is advocated. It is suggested that the keeping of bees may be made a means of retaining the boys on the farm.

**Feeding back extracted honey**, G. M. DOOLITTLE (*Amer. Bee Jour., 37 (1897), No. 37, pp. 578, 579*).—It is thought by the author that those who think feeding back

<sup>1</sup>See F. W. Konow, *Tenthredinidae Europae*, *Dent. Ent. Ztschr.*, 1890, p. 239.

is a failure outnumber those who think the contrary. From his own experience he concludes that if anyone must feed back he had best do so in the spring so as to hasten brood rearing and at the proper time put on the sections; but he does not think the practice will pay in the long run since it is on the principle of producing two crops to get one.

**Preparing honey for the market**, G. M. DOOLITTLE (*Amer. Bee Jour.*, 37 (1897), No. 34, pp. 529-530).—It is recommended that honey should be kept in a dry room where the temperature will be sufficient to ripen it (85 to 90°). This high temperature will cause the eggs of the moths to hatch, if there are any, so that daily inspection of the sections will enable one to discover and destroy the larvæ. This may be done by sulphur fumes.

**The new Hoffman frame for 1897**, E. R. ROOT (*Amer. Bee Jour.*, 37 (1897), No. 9, p. 132, figs. 7, from *Gleanings in Bee Culture*).—In this new frame the ends of the top bars are so constructed and hung as to allow bee spaces all around them. End play is prevented by small staples driven in just below the top bar and striking against the rabbet as the frames hang in position. In such a device the trouble from propolis is reduced to a minimum so that the frames may be handled easily without the aid of a pry.

**Some advantages of a bee space**, W. C. GATHRIGHT (*Amer. Bee Jour.*, 37 (1897), No. 36, pp. 562, 563).—This article is an answer to an article defending the non-use of bee spaces at the ends of frames. A bee space serves a good purpose when one has to handle a large number of bees and time is valuable. Further, in warm weather such spaces are an aid in ventilation.

**Injurious insects in Norway, 1896**, W. M. SCHÖYEN (*Aarsber. Offent. Foranst. Landbr. Fremme*, 1896, pp. 61-116).—The illustrated report of the State entomologist of Norway for the year 1896.

**The ox warble**, C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Circ. 25, 2. ser.*, pp. 10, figs. 10).—The author discusses popularly the general characteristics and origin of the ox warble, *Hypoderma lineata*, contrasting it with the warble fly, *Hypodermis boris*, of Europe. He states that it has been estimated that the damages shown in the depreciation in the value of hides has amounted to as much as \$500,000, to which is to be added the depreciation in the quality of beef in infected animals. Miss Ormerod is quoted as authority for the estimate that the warble of Europe causes damages amounting to from £2,000,000 to £7,000,000 per annum. The life history and habits are described somewhat at length and the common remedies, known from the time of Pliny to the present, of smearing strong smelling oils and fats on the animal to prevent the fly from depositing its eggs as well as to kill the larvæ in their final stages noted. The method of removing the grubs by means of tweezers is thought best.

**Notes on certain Coleoptera known to attack the Gypsy moth** (*Agr. Massachusetts*, 1896, pp. 412-433, pls. 3).—The author discusses the local distribution of *Calisoma* and *Harpalus* and the habits of several species of the former genus. The insects were reared in cages and in jars with about 2 in. of earth at the bottom and covered with muslin held in place by rubber bands—a pair of beetles being placed in each jar—and in a box 24 by 5 in. in size sunk in the ground. None of the methods proved thoroughly satisfactory, but eggs were finally obtained from specimens in the jars. From these the author was finally able to learn that the egg stage of *Calisoma frigidum* lasts from 4 to 10 days, the second larval stage from 4 to 11 days, and the third larval stage about 21 days, and that the egg stage in *C. callidum* lasts about 11 days; the first, second, and third larval stages 7, 7, and 30 days, respectively.

**The two lined chestnut borer**, F. H. CHITTENDEN (*U. S. Dept. Agr., Division of Entomology Circ. 24, 2. ser.*, pp. 8, fig. 1).—This is a recompilation of matter relating to *Agrilus bilineatus* that appeared in Bulletin 7, n. ser., of the Division of Entomology (E. S. R., 9, p. 669), with the addition of some new matter. The insect is noted as having been reported from the District of Columbia, Virginia, West Virginia, Illinois, Wisconsin, and Michigan, and as being probably dangerous in parts of Maryland,

Pennsylvania, Ohio, Kentucky, North Carolina, and Tennessee. In the District of Columbia the adult insects appear in May and the early part of June and deposit their eggs. *Spathius simillimus* is noted as an undoubted parasite of this borer.

After the borers once attack a tree it is impossible to save it. The methods of extracting the round headed beetle from the tree are in this case scarcely practicable. The chief reliance must be on preventive measures, such as clean culture, cutting down and burning dead or injured trees, the making of trap trees, and coating the trunks with a mixture of clay or manure or with Raupenleim. Storm killed trees should be removed, and sawn timber should not be allowed to season without removing the bark; even the family woodpile may form a nidus for the development of the insects. Wood cut in winter and allowed to season over summer should be disposed of before the following April.

**The pear borer,** MATSUMARA (*Annot. Zool. Japan, 1 (1897), pp. 1-3, pl. 1: abs. in Jour. Roy. Micros. Soc. [London], 1897, No. 5, p. 379*).—The life history of *Nephopteryx rubrizonella*, the larger pear borer of Japan, is described. This insect destroys from 30 to 50 per cent of the fruit every year. It is a micro-lepidopterous insect of the group Pyradina and of the family Phycidae.

As remedies, cutting off the branches bearing the eggs, the use of kerosene emulsion, and as a last resort pouring carbon bisulphid into the hole made in the fruit, are mentioned as being employed.

**The buffalo tree hopper,** C. L. MARLATT (*U. S. Dept. Agr., Division of Entomology Circ. 23, 2. ser., pp. 4, figs. 2*).—A popular description of the buffalo tree hopper (*Cercsa bubalus*), its habits, life history, and damages. Vigorous pruning in the fall and the planting of trap crops are recommended as remedies.

**Notes on the life history and habits of certain predaceous heteroptera,** A. H. KIRKLAND (*Agr. Massachusetts, 1896, pp. 399-411, pls. 2*).—The life histories of several hemiptera (*Podisus placidus, Dendrocoris humeralis, Diplodus luridus*, and a new species, *Euschistus politus*). A pair of the new species was discovered by the author in Massachusetts, and since then others have been obtained from Rhode Island, Pennsylvania, the District of Columbia, and Maryland. This species does not seem to be common. As an enemy of the gypsy moth this insect is of minor importance, and the author adds that from the structure of its beak he is inclined to believe it is more of a plant feeder than a destroyer of insects.

**The suppression of insect pests and plant diseases by legislation,** B. T. GALLOWAY (*U. S. Dept. Agr., Proc. Natl. Convention for the Suppression of Insect Pests and Plant Diseases by Legislation, held at Washington, March 5-6, 1897, pp. 31*).—This contains a complete report of the proceedings of the meeting and the text of the bill which has already been referred to (E. S. R., 8, p. 913), as well as a synopsis of papers read at the meeting. In the paper read by L. O. Howard it was shown that the principal places of entry to be guarded are Boston, Charleston, New York, St. Augustine, Key West, Tampa, New Orleans, and Baltimore. A paper by B. F. Delong set forth the plan for inspection, etc., followed in California. This was followed by a paper on "Crop pests and their repression by law" by G. McCarthy, which states that of the 3 classes of farm pests, fungi, weeds, and insects, only the last can be dealt with by national law, and that of such a law a national quarantine, the enforced inspection and certification of plants which are subjects of interstate commerce are the principal desiderata. In the discussion that followed the papers, the difficulty of inspecting fruits put up in boxes, etc., was brought out, but this difficulty it was thought might be overcome by requiring all such goods to be packed in boxes with easily removable covers.

**Notes on some chemical points in the preparation of insecticides and fungicides,** F. B. GUTHRIE (*Agr. Gaz. New South Wales, 8 (1897), No. 10, pp. 707-715*).—Among the points most worthy of note is that in making Bordeaux mixture the lime water should be poured into the copper solution and not the latter into the former. The lime should be fresh. Free copper sulphate, even in small quantities, burns the foliage and therefore should not be allowed to be present.

The blue stone is sometimes impure owing to the presence of sulphate of iron. Iron vessels should be avoided as containers for this mixture; wooden vessels are preferable.

In making lime, salt, and sulphur wash, the sulphur may be thoroughly incorporated by first grinding it up into a paste with a small quantity of water. The best vessel for boiling the mixture is an enameled one.

Speaking of kerosene emulsion he states that free oil is injurious to foliage and that it attacks India rubber; hence it is necessary to wash out the spraying apparatus with hot water after use.

**Spraying fruit trees with Paris green as a remedy against larvæ, W. M. SCHÖYEN** (*Ent. Tidskr.*, 12 (1896), pp. 216-220).

**Insecticides and fungicides, a guide to their application in agriculture and horticulture, W. M. SCHÖYEN** (*Insekt- og sopfordrivende Midler. Christiania: Grøndahl & Søn, 1896, pp. 16*).

**A simple and cheap apparatus for making kerosene emulsion, W. M. SCHÖYEN** (*Norsk Hæretidende, 13 (1897), No. 4, pp. 56-58*).

**Caution against the use of kerosene in the treatment of Pediculosis capitis, M. E. PAUL** (*Lancet [London], 2 (1897), No. 3874, p. 1385*).—The caution is against the danger of fire. A case is cited in which death was brought about not from the hair becoming ignited from a naked light, but, as explained by Lord Kelvin, from an explosive mixture of air and kerosene vapor having been formed in the interstices of the hair which was ignited by an electric spark produced by friction of the hair.

**A new application of carbid of calcium, E. CHUARD** (*Chron. Agr. Cant. Faud, 9 (1896), pp. 207-209*).—The author notes briefly the peculiarities of this substance, its production from acetylene, during the evolution of which the carbid becomes transformed to quicklime and later to slacked lime, if there is sufficient water present. As acetylene has insecticidal properties, he points out that one has in carbid of calcium a substance that may be used as an insecticide and at the same time serve as a mineral manure.

**Rörig's lamp for the destruction of insects** (*Sci. Amer. Sup. 44 (1897), No. 1135, p. 18145, fig. 1, from La Nature*).—This inexpensive apparatus consists of a hexagonal lantern tapering pyramidally above and below, inclosing a lamp and provided with 6 apertures and as many strong lenses, each preceded with a conical reflector, through which insects attracted by the light may enter. The pyramidal top is provided with ventilators that allow proper ventilation without permitting the escape of the insects. These are attracted below by a saccharine or odoriferous mixture contained in a department in the pyramidal base. At the bottom of this base is a large receptacle into which the insects fall and from which they may be gathered from time to time.

The diameter of the lantern is 0.31 meter; the sides 0.15 meter square. The front aperture is 0.13 meter. The apparatus is supposed to be placed in a field or in a tree.

**Foul brood, Pickle brood or new disease, E. S. LOVESY** (*Amer. Bee Jour., 37 (1897), No. 27, p. 419*).—A bee disease is noted as occurring in Utah that resembles foul brood sufficiently to be sometimes mistaken for it; but, according to the author, is distinguished from it by a number of peculiarities. It first made its appearance in the spring of 1896 and spread with great rapidity—more so than foul brood—from hive to hive and from one locality to another. There appears to be no doubt that it is contagious. It differs from foul brood in lacking the offensive smell of that disease and in not having the stringy or coffee-colored appearance so characteristic of foul brood. It is strictly a disease of the brood, the larvæ dying when nearly full grown and merely shriveling up. When they reach about the size of house flies they are removed from the cells and cast out of the hive. They may usually be drawn from the cell whole, an impossible thing in foul brood.

According to the author's experience the disease ebbs and flows with the condition of the swarm attacked. A vigorous swarm is seldom attacked. Transferring to a clean hive and foundation acts as a cure, and the same result, it is said, may be obtained by sprinkling bees and comb with fine dried salt. The latter remedy is also recommended for holding foul brood in check.

**The real cause of foul brood among bees**, W. McEVoy (*Amer. Bee Jour.*, 37 (1897), No. 23, pp. 356-357).—The author states that foul brood is a disease caused primarily by the rotting of uncared-for brood and the storing of honey in cells in which such brood has existed. It usually appears in the spring in weak colonies that have spring dwindled so badly that there are not enough bees left to cover or care for all the brood. As a consequence the honey stored in the cells noted becomes mixed with the remains of dead brood and when fed spreads the disease. He further remarks that empty hives will not convey the disease nor do queens transmit it.

**Bisulphid of carbon as a foul brood remedy**, C. DAVENPORT (*Amer. Bee Jour.*, 37 (1897), No. 13, p. 195).—After a number of experiments with drugs for the purpose of determining the best remedy for killing moths in comb honey, the author has come to the conclusion that carbon bisulphid is very efficient, the affected combs being placed in a tight receptacle and being fumigated. The carbon bisulphid has the disadvantage of making the honey thinner and ruining the flavor, but the honey may, nevertheless, be used for the bees. The suggestion is made that the remedy might be used for foul brood. A single experiment is recorded in which foul-broody comb 6 or 7 in. square, containing some honey and about one-third of the comb containing dead brood in different stages, was treated with the fumes of carbon bisulphid over night, or about 10 hours, and then placed on the top of the frames of a colony and mashed so that the honey ran down over the bees and brood, with the result at the time of writing that no foul brood had appeared in the colony. It is pointed out that the method of fumigating would be much more economical than the method of destroying the combs, etc. The remedy seems worthy of being given a more extensive trial.

### FOODS—ANIMAL PRODUCTION.

**Losses in boiling vegetables**, H. SNYDER (*U. S. Dept. Agr., Office of Experiment Stations Bul. 43, pp. 7-19, figs. 6*).—Tests were made to determine the losses of nutrients which potatoes, carrots, and cabbages undergo when boiled in a number of different ways, all of which were in accord with household usage. These vegetables were selected as fair representatives of tubers, roots, and salad plants. Analyses of the fresh vegetables are reported. The changes which the different nutrients undergo in cooking are briefly discussed.

The following table shows the average losses which these vegetables undergo when boiled according to the different methods:

*Average loss of ingredients in cooking vegetables.*

Method of cooking.	Dry matter.	Total nitrogen.	Fat and carbohydrates.	Starch.	Sugar.	Ash.
Potatoes:	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Peeled, soaked, and cooked in water cold at start .....	6.5	51.8	.....	.....	.....	38.3
Peeled and cooked in water cold at start .....	3.1	15.8	.....	1.0	.....	18.8
Peeled and cooked in water hot at start .....	3.4	8.2	.....	1.0	.....	18.1
Not peeled and cooked in water cold at start .....	.4	1.0	.....	0.1	.....	3.4
Not peeled and cooked in water hot at start .....	.4	1.0	.....	0.1	.....	3.3
Carrots: <i>a</i>						
Cut in small pieces .....	29.9	42.5	.....	.....	26.0	47.3
Cut in medium-sized pieces .....	23.5	27.5	.....	.....	26.5	37.3

Cooked in water hot at start .....	35.1	35.8	34.3	.....	.....	49.2

*a* The carrots were cooked in water both cold and hot at start. The differences were small and only average figures are given.

"The losses which occur in cooking potatoes, carrots, and cabbage vary with the different methods of boiling followed, being quite considerable in some cases. These losses must be taken into account in computing dietaries and made good by adding other materials to supply the nutrients lost. While the loss is not so great as to render it imperative that people in comfortable circumstances should abandon methods of preparing these foods which they consider make them most palatable, there are very large numbers who can not afford to permit even the comparatively small waste of food observed in these experiments.

"The purpose of experiments, such as those here reported, is to learn what actually takes place in the process of preparing food by the common methods. Those having charge of the preparation of food must determine how far it is desirable under individual circumstances to apply the information obtained."

**The composition of different parts of the potato and the loss of nutrients during the process of boiling, A. J. FRISBY and A. P. BRYANT (U. S. Dept. Agr., Office of Experiment Stations Bul. 43, pp. 25-31, fig. 1).**—The structure and composition of potatoes are discussed at some length. Analyses are reported of the outer or true skin of the potato, the inner skin or fibro-vascular layer, the flesh, and the whole potato. These values are given in the following table:

*Composition of the whole potato and its different parts.*

	Nitrogen.			Protein.	Fat.	Carbohydrates.		Ash.
	Water.	Albuminoid.	Total.			Nitrogen-free extract.	Fiber.	
	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>
Outer, or true, skin.....	80.1	0.25	0.43	2.7	0.8	14.6		1.8
Inner skin or fibro-vascular layer.....	83.2	.24	.36	2.3	.1	12.6	0.7	1.1
Flesh.....	81.1	.18	.32	2.0	.1	15.7	.3	.8
Calculated composition of whole potato.....	81.3	.19	.32	2.0	.1	15.7		.9

In the authors' opinion 5.5 should be used as the protein factor in calculating the protein content of the potato instead of 6.25. The results obtained by the use of the 2 factors are compared. The losses of nutrients which potatoes undergo when boiled in different ways were also determined. The results were as follows:

*The loss of material during the process of cooking potatoes.*

	Dry matter.	Nitrogen.			Carbohydrates.	Ash.
		Albuminoid.	Nonalbuminoid.	Total.		
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Skins removed before boiling:						
Water cold at beginning of test.....	3.7	4.3	12.9	8.3	2.5	17.0
Water hot at beginning of test.....	4.0	3.3	17.9	10.0	2.8	17.4
Average.....	3.9	3.8	15.4	9.2	2.7	17.2
Boiled with skins on:						
Water cold at beginning of test.....	.3	.6	.6	.6	.2	1.9
Water hot at beginning of test.....	.3	.4	1.7	1.0	.1	1.2
Average.....	.3	.5	1.1	.8	.2	1.6

"When potatoes are boiled with the skins removed, there is a very considerable loss not only of organic nutrients but also of mineral salts. These salts, while not nutrients in the sense in which this term is frequently used, are nevertheless important in nutrition. They are of especial value, because of the potassium compounds which they contain, and are apparently necessary for health.

"The greatest actual loss of nutrients seems to be due to the mechanical abrasion of the soft outer portions of the potato while cooking. In this case nearly 3 per cent of the carbohydrates and 4 per cent of the available flesh-forming nitrogenous matter are lost. When the potatoes are boiled with their skins on, the loss of nutrients is very slight, consisting chiefly of nonalbuminoid nitrogenous substances and mineral matter. It is self-evident that if it is desired to boil potatoes with as little loss as possible the skins should be left on."

**The digestibility of potatoes and eggs,** H. SNYDER (*U. S. Dept. Agr., Office of Experiment Stations Bul. 13, pp. 20-21*).—The digestibility of eggs boiled different lengths of time was determined by digesting with pepsin and hydrochloric acid. A test was made with a man weighing 62.5 kg. to determine the digestibility of potatoes when consumed with eggs, milk, and cream. The experiment lasted 4½ days. The food, urine, and feces were analyzed. The feces were separated by means of charcoal taken in gelatin capsules. The daily diet consisted of 1,587 gm. of potatoes, 8 hard-boiled eggs, 710 cc. of milk, and 237 cc. of cream. It was assumed that 97 per cent of the protein and all of the carbohydrates of the milk, eggs, and cream were digested. The amount of fat in the potatoes was so small that no attempt was made to determine its digestibility. Taking these facts into account, the digestibility of the potatoes was calculated from the digestibility of the total food as actually obtained. The digestibility of the whole diet and of the potatoes is shown in the following table, due correction being made for the fuel value of the nitrogen excreted as urea in the urine:

*Coefficients of digestibility of whole food and of potatoes.*

	Total organic matter.	Protein.	Fat.	Carbohy- drates.	Fuel value.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Whole food.....	92.7	88.8	93.3	93.8	89.5
Potatoes.....	90.6	71.9	.....	93.0	83.6

The average daily income of nitrogen in the food was 18.14 gm.; the daily excretion was 15.74 gm. in the urine and 2.03 gm. in the feces. Therefore there was a daily gain of 0.37 gm. of nitrogen. This was calculated to be equivalent to 9.88 gm. of protein or 43 gm. of muscle.

**The losses and chemical changes which vegetable feeding stuffs undergo when kept for a long time at a high temperature,** H. WEISKE (*Landw. Vers. Stat., 48 (1897), No. 6, pp. 379-389*).—A number of samples of medium quality meadow hay were kept in glass jars in a drying oven at 100° for 6 months. Some of the jars were simply covered with filter paper. Twenty-four hours after placing in

the oven the contents of a number of the jars were wet with 25 cc. of distilled water. The jars were then stoppered with corks, except one which was closed with a glass stopper. The hay in the latter remained moist longer than that in the others. After 2 weeks or 1 month, and later at intervals of 1 month, samples of the contents of the different jars were analyzed and the digestibility determined by the Stutzer method. The following table shows the composition and digestibility of the nitrogen of samples of hay preserved by the 3 methods:

*Composition and digestibility of hay preserved in different ways.*

	Protein.	Albumi- noid nitrogen.	Fat.	Crude fiber.	Nitrogen- free extract.	Ash.	Digesti- bility of nitrogen.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Normal hay .....	12.32	1.86	3.84	22.64	52.46	8.74	1.21
Hay kept at 100° in open jars:							
2 weeks .....	13.00	.....	3.27	21.32	53.70	8.71	.73
1 month .....	13.75	1.96	1.89	21.21	54.69	8.56	.40
2 months .....	14.12	.....	2.09	20.19	55.35	8.33	.58
3 months .....	13.19	2.00	1.71	20.17	56.41	8.52	.36
4 months .....	12.81	.....	1.71	18.72	57.92	8.84	.33
5 months .....	13.29	.....	1.59	20.42	56.09	8.61	.31
6 months .....	13.63	2.03	2.11	18.55	57.06	8.65	.46
Hay moistened and kept at 100° in jars stoppered with cork:							
1 month .....	13.63	2.03	2.51	18.19	56.50	9.17	.26
2 months .....	13.37	.....	2.03	19.69	56.08	8.83	.28
3 months .....	13.63	2.00	1.62	17.62	57.53	9.60	.14
4 months .....	13.69	.....	1.67	16.86	58.37	9.41	.19
5 months .....	14.62	.....	1.81	16.77	57.27	9.63	.34
6 months .....	14.31	1.98	2.07	17.56	56.44	9.62	.25
Hay moistened and kept at 100° in a jar with glass stopper:							
1 month .....	15.06	.....	3.30	14.61	57.41	9.62	.27

Among the conclusions reached are the following: When meadow hay is kept for a long time at 100° there is no marked change in the amount of albuminoid and non-albuminoid nitrogen. On the other hand, the proportion of digestible and indigestible protein is affected. The amount of digestible protein is diminished and the amount of indigestible protein increased even when kept at this temperature only 2 weeks to 1 month. This change was somewhat more marked in the hay which was moistened than in that not moistened. After about 6 months no further change was observed in either sort. That the diminution in the digestibility is due to some deep-seated change in the protein and not to simple coagulation is shown by the fact that when kept at 100° for 4 days the digestibility of protein of the hay was not diminished, though the period was sufficiently long to produce coagulation. It is probable that the digestibility and nutritive value of the other nutrients is also somewhat diminished by keeping hay for a long time at 100°.

**The influence of muscular work on metabolism of dogs, N. ZUNTZ** (*Arch. Physiol. [Pflüger]*, 68, No. 5-7, pp. 191-211).—A number of experiments are reported with a dog under various conditions of rest and work. The work done was measured by means of apparatus similar to that described in a previous publication.<sup>1</sup> The respiratory quotient, *i. e.*,

<sup>1</sup>Landw. Jahrb., 1889, p. 7.

the ratio of inspired oxygen to respired carbon dioxide, was determined. A tube provided with suitable valves was inserted in the trachea. The dog could breathe only through this tube. The amount of inspired and expired air was measured. The experimental methods followed are reported in detail.

The principal conclusions reached were the following: In normal work all the Mammalia with which experiments have been made have been found to require practically the same amount of chemical energy for the unit of work. A little more than a third of the chemical energy furnished by the food can serve for the production of external muscular work. The rest is transformed into heat. When the work performed consists in pulling, the proportion of the energy of the food which is effective is somewhat less than when the energy is expended in climbing an incline, and the proportion decreases with increased work. The smaller the animal the greater the energy required for forward progression of a like mass through a like distance. The energy expended is very nearly proportional to the surface area of the body.

**Contribution to the question of the source of muscular energy,** J. FRENTZEL (*Arch. Physiol. [Pflüger]*, 68, No. 5-7, pp. 212-221).—Two experiments were made with dogs. In the first test the food furnished an abundance of fat and protein. During the first few days of the second test the dogs consumed fat only and during the remainder they fasted. The excretion of nitrogen in the urine under various conditions of work and rest was determined. The amount of work performed was measured as in the experiments by Zuntz, noted above (p. 680). The amount of protein which was broken down in the body was computed from the amount of nitrogen excreted in the urine. The energy which this protein would furnish was also calculated. These values were compared with the figures obtained by measuring the energy produced.

The following deductions were drawn: When fat only is consumed or when the subject is fasting, work is performed chiefly at the expense of the fat in the food or fat in the body. Using the data mentioned above, protein could not be regarded as the sole source of muscular energy.

**Further investigations on the fat in muscular tissue,** E. BODANOW (*Arch. Physiol. [Pflüger]*, 68, No. 8-9, pp. 408-430, figs. 3).—The author has continued the work previously reported,<sup>1</sup> paying special attention to testing the accuracy of the different steps in the method followed in extracting and estimating the fat in meat. Experiments were also made with frogs and rabbits to study the influence of muscular work on the kind and amount of fat contained in the muscles.

The conclusions drawn from earlier work are, in the author's opinion, confirmed, namely, that muscular tissue contains 2 kinds of fat of fairly constant composition, one which may be easily extracted with ether and the other extracted with difficulty. The latter, the so-called plasma fat, has a high percentage of fatty acid. Fat is regarded as the immediate source of muscular energy.

<sup>1</sup> *Arch. Physiol. [Pflüger]* 65, p. 81 (E. S. R., 8, p. 713).

**Grain rations for fattening sheep, J. H. SHEPPERD** (*North Dakota Sta. Bul.* 28, pp. 165-175).—To determine whether it is not more profitable to fatten sheep on inexpensive feeding stuffs available in the local market than to ship them from the range a test was made with 4 lots of range wethers. Lots 1 and 3 consisted of 5 sheep each and lots 2 and 4 of 4 sheep. The test, which began February 9, was divided into 3 periods of 4 weeks each. The periods were separated by several days. Lot 1 was fed oats and timothy hay, lot 2 wheat screenings and timothy hay, lot 3 barley and bran (3:1) and timothy hay, and lot 4 barley and bran (3:1) and oat straw. The screenings were made up of 33 per cent shrunken wheat, 27.9 per cent wild buckwheat, 11.6 per cent straw, 2.5 per cent oats, 4.2 per cent foxtail, and 20.8 per cent mixed weed seed. For a month before the beginning of the test the sheep had been given a heavy grain ration, and the test proper was preceded by a preliminary period of 10 days on the rations used during the experiment.

The financial statement is based on oats at 25 cts. and barley at 35 cts. per bushel and bran at \$10, screenings at \$6, timothy hay at \$5, and oat straw at \$1 per ton.

The cost per pound of gain for the different lots was as follows: Lot 1, 5.96 cts.; lot 2, 5.22 cts.; lot 3, 4.48 cts., and lot 4, 4.93 cts.

A month after the close of the test the sheep were sold for  $4\frac{1}{2}$  cts. per pound. On this basis the average profit per head for all the lots was \$2.14. The author believes that wheat screenings and bran may be profitably fed to sheep under local conditions.

Among the conclusions drawn from the experiment are the following:

“The best gain was made on a ration of unground oats and timothy hay. A ration consisting of 3 parts barley and 1 part bran, by weight, with timothy hay, made the second best average of  $2\frac{1}{4}$  lbs. per head per week. Oat straw fed as a substitute for timothy hay gave  $\frac{1}{2}$  lb. less gain per head per week. The lot fed straw ate a much larger proportion of grain to produce a given gain, however, which made the cost per 100 lbs. of gain 45 cts. greater than in the lot fed hay. Sheep fed screenings and timothy hay made the lowest rate of gain, an average of 2 lbs. per head per week. The lot fed screenings required more hay than any other lot which was fed hay. The gain in the lot fed screenings cost 74 cts. per 100 lbs. more than the lot fed barley and bran with hay.”

**Fodders and feeds** (*New Jersey Stas. Rpt.* 1896, pp. 122-125).—Analyses are given of crimson clover, cowpea vines, green rye, rape, corn silage, hay, wheat bran, wheat middlings, dried distillery grains, dried brewers' grains, linseed meal, improved Buffalo gluten feed, Chicago gluten meal, hominy meal, oat feed, nutriotone, and apples.

**Average composition of fodders and feeds** (*New Jersey Stas. Rpt.* 1896, pp. 127-133).—This includes a compilation of analyses (food and fertilizer constituents) of the more common feeding stuffs.

**Market prices of commercial feeds** (*New Jersey Stas. Rpt.* 1896, pp. 126, 127).—The cost of a number of feeding stuffs from 1891 to 1896 is given in tabular form.

**Feeding stuffs inspection**, C. D. WOODS (*Maine Sta. Bul.* 37, pp. 8).—This contains the text of the Maine feeding stuffs law and briefly points out its chief provisions.

**On feeding Indian corn to farm animals**, F. FRIS (*Landmansblade*, 30 (1897), No. 24, pp. 319-322).

The length of time which food remains in the digestive apparatus of rabbits, H. WEISKE (*Landw. Vers. Stat.*, 48 (1897), No. 6, pp. 375-378).—The author concludes, as the result of a number of experiments, that when rabbits are fed coarse fodder, following a diet of grain, the intestinal tract is probably very free from grain (more or less completely digested) in about 2 days.

Elements of physiology of domestic Mammalia, H. HORNE (*Grundtrök af huspattedyrenes fysiologi*. Christiania: Gröndahl & Sön, 1897, pp. 100).

Farm poultry (*Kansas State Bd. Agr. Rpt.* 1897, Mar. 31, pp. 256, figs. 33).—This contains statistics of poultry products sold in the State of Kansas during 1895 and 1896; and articles on breeding, management, and marketing with special reference to local conditions, together with addresses and discussions at the annual meeting of the Kansas State Board of Agriculture, January 13-15, 1897.

A new law of heredity, F. GALTON (*Nature*, 56, No. 1445, pp. 235-237).—An application of the law, given in the author's *Natural Inheritances*, to a collection of 817 hounds of registered colors, from parents whose colors were known.

## DAIRY FARMING—DAIRYING.

Feeding experiment with linseed oil and ground flaxseed on cows, D. MELIK. BEGLARIAN (*Milch Ztg.*, 26 (1897), No. 33, pp. 522, 523).—The author refers to Soxhlet's recent work, in which it was claimed that the fat content of milk might be increased by feeding fat (linseed oil, etc.) in digestible form (E. S. R., 8, p. 1016). He reports an experiment made at the farm of the agricultural academy at Poppelsdorf with 4 cows, covering 4 periods of 8 days each. In the first and last periods the ration was the same, consisting of 50 kg. of beets, 14 kg. of hay, 3 kg. of straw, 4 kg. of malt sprouts, 4 kg. of linseed meal, and 2 kg. of barley meal per 1,000 lbs. live weight. In the second period 1 kg. of linseed oil was added per cow daily, being emulsified by treating with water in a cream separator, and in the third period the oil was dropped and 4 kg. of ground flaxseed was fed in place of the linseed meal of the basal ration. Cows 1 and 2 took the linseed oil readily from the first, but cows 3 and 4 had to become accustomed to it. There was a falling off in the appetites of all the cows when the oil was fed, and they refused to eat the basal ration up clean.

The average milk yield and specific gravity and fat content of the milk of each cow for the last 3 days of each period are tabulated. While on linseed oil all the cows shrank in milk yield, and the yield increased when put upon flaxseed. Except in one case the fat content increased on linseed oil, the average increase being 0.23 per cent. It diminished on the flaxseed ration. The author considers there is nothing remarkable in the increase of 0.23 per cent in the second period, as an equal increase frequently occurs in placing cows upon a less favorable ration accompanied by a falling off in milk. The results are considered entirely negative, as the addition of oil was not accompanied by a noticeable increase in fat content, while it acted unfavorably upon the digestion and the general condition of the cows. The flaxseed was equally unsatisfactory.

The question of the relation between the fat in the food and the fat in the milk, M. MAERCKER (*Milch Ztg.*, 26 (1897), No. 31, pp. 542, 543).—A short note is given on an experiment in which a ration

very poor in fat was fed at first, supplemented later by palm cake and cocoanut cake in separate periods, and later by an especially rich cocoanut cake containing 30.24 per cent of fat. Following this the cows were changed to the ration poor in fat. The results were as follows:

*Fat in food and in the milk.*

Period.		Fat in the food.		Fat content of milk.
		Kg.	Per cent.	
1	Ration poor in fat .....	0.297		3.21
2	Palm-cake ration .....	.437		3.52
3	Ration poor in fat .....	.297		3.20
4	Cocoanut-cake ration .....	.747		3.48
5	Cocoanut-cake ration (very rich in fat) .....	1.706		4.00
6	Ration poor in fat .....	.297		3.23

The author believes that the fat content of the milk was materially influenced by the amount of fat in the rations, but states that with the increase in the fat content the yield of milk was unfavorably affected. The yields in the different periods are not given in full, but it is stated that the average yield on the first cocoanut-cake ration was 14.65 kg. of milk, with an average fat content of 3.48 per cent, and that in the following period, when the richer cocoanut cake was fed, the yield sank to 12.42 kg., with an average fat content of 4 per cent. There was no advantage from feeding the richer ration, as the increase in fat content was not sufficient to overcome the decrease in yield. The rations rich in fat had a marked effect on the increase in live weight of the cows.

**Experiments in milking twice and four times daily,** BACKHAUS (*Königsberger Land- u. Forstw. Ztg.; abs. in Milch Ztg., 26 (1897), No. 41, p. 654*).—A short experiment is reported with 8 cows, the results of which are summarized below.

*Comparison of milking twice and four times a day.*

	Total yield of 8 cows.			Average composition of milk.	
	Milk.	Fat.	Solids-not-fat.	Fat.	Solids-not-fat.
Cows milked twice a day (June 21-24) .....	524.60	17.04	45.47	3.25	8.67
Cows milked 4 times a day (June 28-31) .....	576.70	17.95	49.57	3.11	8.60
Percentage increase from milking 4 times a day .....	9.93	5.34	9.01		

Milking 4 times a day gave a larger yield of both milk and fat than milking twice a day. Contrary to the usual rule, milking 4 times a day gave the poorer milk. To test this further the experiment with milking 4 times a day was continued, the cows receiving a richer ration. On an average the 8 cows showed an increase of 5.36 per cent in the yield of fat, but only 0.44 per cent increase in the yield of milk and 0.65 per cent in the yield of solids-not-fat over milking twice a day. It was found further that when the time between milkings was divided equally the milk did not have the same composition, the milk being

poorer in fat after the cows had been at rest, as at night, while after they had been in active motion, feeding, etc., the fat was higher. This is said to agree with the results obtained when cows are worked.

**Proportion of ash and phosphates in cows' milk, L. VAUDIN** (*Ann. Chim. Analyt. et Appl.*, 2 (1897), pp. 341-347; *abs. in Analyst*, 22 (1897), Nov., p. 282).—From analyses of the milk of several different breeds of cows fed on a variety of fodder, the author concludes that in normal milk the percentage of ash ranges within the limits of 7 and 8 gm. per liter, of which 3.3 to 4 gm. consists of phosphates (lime, magnesia, and iron) precipitable by ammonia. This is independent of breed, soil, daily yield, etc., but the individuality of the animal and the diet exercise a slight influence on the proportions between the above limits. On the other hand, in milk rendered abnormal by pathological or other influences, the percentage of ash and proteid bodies is increased, but in an irregular manner. For example, in the case of a pregnant cow the milk contained 52.16 per cent of albuminoids and 8.6 per cent of ash, and that from one poisoned by oil cake infested with *Aspergillus*, 44 and 8.5 per cent, respectively; whereas in two instances the albuminoids of normal milk amounted to only 36.3 and 41.6 per cent.

**Concerning the phosphorus in human milk and cows' milk, J. STOKLASA** (*Ztschr. Physiol. Chem.*, 23 (1897), No. 4-5, pp. 313-316).—The author finds that aside from the phosphorus in the casein and nuclein, milk contains considerable phosphorus in the lecithin. He finds the lecithin content of milk higher than previously reported. The range per liter is 0.90 to 1.13 gm. for cows' milk, and 1.1 to 1.3 gm. for human milk. Analyses showed human milk to contain 0.44 gm. of phosphoric acid (as  $P_2O_5$ ) per liter and cows' milk 1.81 gm. Accordingly it is calculated that human milk contains per liter 0.153 gm. of  $P_2O_5$  as lecithin, while cows' milk contains only 0.091 gm., these amounts representing 35 per cent of the total  $P_2O_5$  in human milk and 5 per cent of that in cows' milk.

Siegfried gave the nuclein content per liter as from 0.55 to 0.6 gm. for cows' milk, and from 1.1 to 1.3 gm. for human milk.

The author calls attention to the analogy between milk and the embryo of the seeds of some plants with respect to the form of the organic phosphorus.

**Composition of the milk of Oldenburg breeding mares, P. PETERSEN and H. HÖFKER** (*Milch Ztg.*, 26 (1897), No. 41, pp. 647, 648).—The authors made analyses of the milk of 3 mares at different dates after foaling. The maximum, minimum, and average composition of the 10 samples analyzed is given in the following table:

*Composition of mares' milk.*

	Specific gravity.	Water.	Total solids.	Fat.	Nitrogenous matter.	Milk sugar.	Ash.
		<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Maximum.....	1.0405	99.60	10.43	1.07	2.63	7.12	0.48
Minimum.....	1.0334	89.57	9.40	.37	1.56	6.34	.27
Average.....	1.0363	90.18	9.82	.61	2.14	6.73	.35

It is pointed out that mares' milk in comparison with cows' milk is much richer in water and sugar but poorer in fat, nitrogenous matter, and ash. The fat in the analyses given is said to be lower than has usually been found for mares' milk but higher in sugar. It is suggested that this may possibly be due to the fact that the animals were at pasture. In substituting cows' milk for mares' milk in feeding colts the usual recommendation to dilute with water and add sugar is believed to be questionable. It is believed to be better not to add any sugar, but to dilute the milk about one-half at first and about one-third later. It is shown that as the period of lactation advances the percentage of both nitrogenous substance and salts decreases while the sugar increases.

**Milk: Composition, nature, hygienic and economic methods of handling,** A. J. McCATCHIE (*Southern California Acad. Sci. Agl. Expt. Section Bul. 3, pp. 29*).—This is a popular bulletin, with the results of some experimental work.

Analyses are given of samples of milk from 8 dairies, together with a record of tests of milk delivered in Los Angeles during the months of June, July, and August. Numerous experiments are briefly reported showing the large number of bacteria in the milk from the first part of the milking ("fore milk"), the bacteria which fall from the cow during milking, the number of bacteria in the air of stables, the bacteria in dairy utensils, the reduction of bacteria in milk by careful milking and handling, the effect of high and low temperatures, cases of gaseous fermentation of milk, bitter milk, and ropy milk. A case of bitter milk was entirely remedied by painting the room in which the milk and cream were kept and observing more cleanly methods. A bad case of ropy or stringy milk was investigated. The condition of the stables, the dairy utensils, and the clothing of the milkers was found to be bad.

"While milk drawn in the ordinary way into unsterilized vessels invariably became ropy, in no case did ropiness ensue when the milk was drawn from these same cows with precautions that prevented the entrance of many living bacteria. Even cleansing the teats and udder with plain water and milking into a sterilized pail covered with cloth to exclude dust prevented ropiness."

The ropiness was communicated to other milk by adding a little of the infected milk. It was found that the milk from some of the cows had a greater tendency to become ropy than that from others, and experiments indicated "that the exterior of some of the cows was infected with the bacteria causing trouble more than the others; and that even the canals of the teats of one cow were infected, as indicated by the fact that her milk became ropy though the exterior had been carefully cleansed. The other 23 cows were tested and the milk from none of them became ropy when drawn with antiseptic precautions." The cause of the trouble, although apparent to the author, was not removed on account of a lack of appreciation of the importance of cleanliness and the failure on the part of the proprietors to fully cooperate with the author.

In conclusion the milk ordinance of the city of Los Angeles is given.

**Milk: Its decomposition and preservation**, R. R. DINWIDDIE (*Arkansas Sta. Bul.* 45, pp. 49-77, pls. 3, figs. 3).—The first part of the bulletin has to do with the spontaneous changes occurring in milk, the sources of bacterial infection, and methods of preserving milk. Some data are given as to the number of bacteria in milk, based on observations by the author, accompanied by a popular discussion of the subject of milk fermentations, the control of the souring of milk, methods of sterilizing, etc.

The second part reports some investigations on the species of bacteria more commonly concerned in the souring of milk in the locality. The milk from 2 dairy farms in the vicinity of the station was examined from October to March and 2 samples of milk were obtained from dairies in other parts of the State. The bacteria found in the souring milk were classed under 3 heads: (1) those which occasioned a rapid souring and complete coagulation, (2) those which produced only a partial curdling with or without acidity, and (3) those which multiplied in the milk without curdling either with or without acidity. Two representatives of the first group are illustrated and described. For one of these, which the author believes to be a hitherto undescribed species, he proposes the name *Bacterium lactarii*. Its characteristics are described in detail.

**Experiments with pure cultures for ripening cream**, P. VIETH (*Milch Ztg.*, 26 (1897), No. 33, pp. 519-521).—The author reports a number of experiments made at different seasons of the year with Witte's and von Lorentz's cultures. Control experiments were also made. The butter was kept for two or three months and then tested as to quality. In general the butter made with the Witte cultures was better than that made without, as it changed less in keeping. The von Lorentz cultures had no apparent good effect on the butter as compared with no cultures.

The author concludes that in these experiments, as in his previous experiments, there was in general no unmistakable and universal improvement in the quality or the keeping properties of butter from using pure cultures. He states it as the general opinion of creameries that pure cultures materially improve the quality of the butter, but mentions that they are employed in creameries especially when some butter fault appears. He believes that pure cultures are chiefly of value in cases of butter faults, and intimates that the difficulty might frequently be avoided or remedied by scrupulous cleanliness and employment of low temperatures.

**Action of beer yeasts on milk**, E. BOULLANGER (*Ann. Inst. Pasteur*, 11 (1897), p. 720; *abs. in Chem. Ztg.*, 21 (1897), No. 89, *Repert.*, p. 257).—There has been some difference of opinion as to whether yeasts in some cases act upon not only the milk sugar but the casein of milk also. The effect was studied of 8 different beer yeasts on sterilized milk. During the first 3 months the appearance of the flasks was

about the same, after which a gradual change became apparent. After 14 months the experiment was discontinued and microscopical and chemical examinations made of the contents of the flasks. It was found that the different kinds of yeasts acted upon the casein in the same relative proportion that they were able to liquefy gelatin. In some cases the casein was dissolved but not further changed, and in others it was more or less decomposed.

**Annual report of the chemist, W. C. ROBINSON, JR.** (*Annual Report of the Chief Inspector of Milk and of the Chemist of the Board of Health of the City and Port of Philadelphia, 1896, pp. 24-59*).—This contains a discussion of the detection of the addition of water to milk, methods of milk analysis, test for coloring matter and preservatives in milk, a discussion of butter and margarin and other food products, and analyses of a large number of samples of water.

Two samples of human milk were analyzed with the following results:

*Analyses of human milk.*

	No. 1,268.	No. 1,509.
Total solids.....	Per cent. 12.72	Per cent. 11.83
Fat.....	5.58	3.30
Milk sugar.....	6.10	5.80
Albuminoids.....	1.04	2.73
Mineral matter.....	.11	.23

“The former was probably drawn from the glands when nearly empty, and the latter when full.”

A sample of goat's milk had the following composition:

*Analysis of goat's milk.*

	Per cent.
Total solids.....	16.33
Fat.....	5.85
Albuminoids.....	4.49
Milk sugar.....	5.11
Mineral matter.....	.88

“A very rich milk.”

**Cost and composition of milk in cities in New Jersey** (*New Jersey Stat. Rpt. 1896, pp. 134-157*).—This is practically a reprint from U. S. Dept. Agr., Office of Experiment Stations Bulletin 35 (E. S. R., 9, p. 80).

**Comparison of the yields and economy of the Ayrshire and native (Telemark) breeds of cattle at Aas Agricultural College, 1860-1896, H. ISAACHSON** (*Ber. Höiere Landbr. Skole i Aas, 1895-'96, pp. 43-94*).

**The results of crossing between the Allgan and the Norrland mountain breeds, J. BRUN** (*K. Landw. Akad. Handl. Tidskr., 36 (1897), No. 3, pp. 198-201*).—The average yield of milk for 6 years (1888-'93) for a herd of 22 cows was 2,421.1 liters. No analyses of the milk produced are given.

**On the feeding of milch cows, H. NATHORST** (*Tidskr. Landtmän, 18 (1897), Nos. 21, pp. 367-371; 22, pp. 385-388*).

**Does Wolff's standard ration for milch cows fill the demands of a modern and scientifically exact standard? E. O. ARENANDER** (*Tidskr. Landtmän, 18 (1897), Nos. 9-14, pp. 145 et seq.*).—Answered in the negative.

Are Wolff's feeding standards antiquated? H. NATHORST (*Tidskr. Landtmän*, 18 (1897), No. 19, pp. 331, 337).—Reply to E. O. Arenander's articles in previous numbers of the *Tidskrift*.

Modern fodder tables and feeding standards for milch cows with different milk yields, E. O. ARENANDER (*Tidsenliga fodertabeller jämte Utfordringsnormer för mjölkande kor*. Stockholm, 1897, pp. 28; extracts in *Landtmannen*, 8 (1897), Nos. 7, pp. 89-94; 8, pp. 103-107).

Report of the periodical butter exhibitions in Hango (Finland), 1896-'97 (*Helsingfors*, 1897, pp. 46).—Eight exhibitions, in all essentials similar to the Danish periodical butter exhibitions (E. S. R., 5, p. 721; 7, p. 626), were held during the year under the direction of the Finnish Agricultural Department (*Landtbruksstyrelsen*).

Pure cultures in cheese making, O. JOHAN-OLSEN (*Aarsber. Offent. Foranst. Landbr. Fremme*, 1896, pp. 478-489; *Nord. Mejeri Tidn.*, 12 (1897), No. 31, pp. 365, 366).

The principles of cheese making, as viewed from a bacteriological standpoint, G. GROTFELT (*Tidskr. Mjölkhusäll.*, 6 (1897), Nos. 14-28, pp. 53 et seq.; *Nord. Mejeri Tidn.*, 12 (1897), Nos. 19-29, pp. 220 et seq.).

The manufacture of Edam and Gouda cheeses, N. HÖRLYCK (*Norsk Landmansblad*, 16 (1897), No. 27, pp. 306-309).

Swedish "estate-cheese" (herrgårdstost) and Gouda cheese, G. LILJIAGEN (*Nord. Mejeri Tidn.*, 12 (1897), Nos. 16, pp. 183, 184; 17, pp. 195-197).

Milk and its products, H. H. WING (*New York: The Macmillan Co.*, 1897, pp. 230, figs. 33).—This is "a treatise upon the nature and qualities of dairy milk and the manufacture of butter and cheese," designed to give "to the dairymen and particularly to the dairy student in simple, concise form, the principles underlying modern

dairy practice." The object of the author has been admirably fulfilled. The pressing need of a text-book on dairying, suited to use in the class room and for general reading, has been met in a most acceptable manner. Both the scientific and the practical sides of dairying are treated in a popular, concise, and clear style, and the information given is brought well up to date. Beginning with the secretion and the composition of milk, the testing of milk, ferments and fermentations and their control, market milk, and the different stages of butter making and cheese making are treated in logical order, followed by the utilization of by-products of the dairy, butter and cheese factories, and dairy statistics. An appendix contains various useful rules and tests, laws of various States affecting dairy products, and a bibliography of dairy work at the experiment stations. A comprehensive index completes the volume.

**Testing milk and its products**, E. H. FARRINGTON and F. W. WOLL (*Madison, Wis.: Mendota Book Co., 1897, pp. 236, figs. 45, pl. 1*).—This little book treats not only of the testing of milk but the application of the results on the farm and at the creamery and cheese factory. It is intended as "a manual for dairy students, creamery and cheese-factory operators, and dairy farmers." The method of treatment of the subject is very complete and the style is simple and plain. The introduction shows the evolution of the milk test, describing the various tests proposed in this country and abroad. The opening chapter is on the composition of milk and its products, and this is followed, after a chapter on sampling, by a description of the Babcock test, method of making the test, modifications, apparatus, calibration, etc., and descriptions of various forms of the test on the market. The lactometer and its application, testing the acidity of milk and cream, and testing the purity of milk are next treated; followed by chapters on the application of the milk test on the farm in improving the herd, composite sampling, cream testing at cream-gathering creameries, calculation of the butter and cheese yields from the results of test, and the calculation of dividends at creameries and cheese factories. The final chapter is on the methods of chemical analysis of milk and its products. An appendix gives various useful tables to facilitate calculations, and suggestions regarding the organization of coöperative creameries and cheese factories; and is followed by a good index. The book is the most complete treatise on the subject of milk testing in a broad sense yet published, and should prove a very useful handbook.

## VETERINARY SCIENCE AND PRACTICE.

**Report of the biologist**, J. NELSON (*New Jersey Stat. Rpt. 1896, pp. 235-285*).—Observations were made on the temperature fluctuations of cows, and a series of temperature experiments begun in 1894 were completed; studies were begun on the curative effect of repeated injections of tuberculin, and on the germ content of milk.

*Experimental work* (pp. 236-262).—In a general way, the effect of repeated injections of tuberculin is discussed, and the fact noted by Bang that different animals react differently and that the same animal at different times reacts very irregularly is brought out and shown to need further study. Some animals react when no tuberculosis can be found; some react only after a number of injections, others repeatedly, and still others upon the first and third injection but not upon the second. The lack of reaction or of a lowered reaction is considered a doubtful indication of a curative process from the fact that badly affected cows often give no response to the test.

As to the curative effect of tuberculin, the author concludes that the

effect is exercised in a very desultory manner. Sometimes it appears to cure, sometimes to retard the disease, and in others to hasten it. Illustrative of this last fact, the case is cited of a cow that began to show signs of failing health and after the ninth test was slaughtered and found more or less badly infected in nearly all the organs. In another instance a cow that had received 12 injections appeared at the time of writing none the worse.

Relative to the germ content of milk, the fact is brought out that the udder is not always affected, even in badly tuberculous animals; nor are the four teats affected in the same degree. It is thought very likely that a few germs may remain in the milk ducts after milking and multiply greatly during the next 12 hours. This would account for the fact that they are in greatest abundance in the first spurts drawn. The greatest average number of germs per drop found in the tests was 649, the lowest 18. In the former case germs were found in great numbers in milk from each of the teats and in every spurt. In the other cases noted, their occurrence in relation to the number of the spurt and to the teat was more or less irregular. The number of germs to the spurt and the relation of this number to the number of the spurt in the series of spurts is well shown by the following table, teat B and C representing the two hind teats:

*Number of germs per drop of the milk of cow 26.*

Number of spurt.	Teat B.			Teat C.		
	Amount in each spurt.	Total amount in spurts drawn.	Number of germs per drop.	Amount in each spurt.	Total amount in spurts drawn.	Number of germs per drop.
One.....	Cc. 5	Cc. 5	10,540	Cc. 2	Cc. 2	11,900
Three.....	8	18	4,420	3	9	2,040
Five.....	10	36	2,380	3	14	1,530
Seven.....	6	49	1,360	2	20	1,140
Nine.....	9	65	2,550	4	27	930
Eleven.....	9	85	480	5	36	740
Thirteen.....	8	103	220	2	43	720
Fifteen.....	5	114	520	3	50	940
Seventeen.....	11	138	440	4	58	1,240
Nineteen.....	7	155	330	4	65	620

*The suppression and prevention of tuberculosis of cattle and its relation to human consumption* (pp. 263–285).—This is a general discussion of the subject. The death rate from the disease, both human and bovine, as shown by statistics from various countries is given, as well as a discussion of what constitutes tuberculosis, its cause, degrees, symptoms; milk as a carrier of the germs, the tuberculin test, and an account of Bang's method.

**Laboratory tests of creolin as a disinfectant**, F. S. ROOP (*Virginia Sta. Bul. 63, pp. 47–52*).—In the experiments with this oily coal tar product, *Staphylococcus pyogenes aureus*—the virulence of which had been tested by its producing death in a rabbit in 24 hours—suspended in water was exposed for varying lengths of time to emulsions of creolin of 2, 1½, 1, and ½ per cent strengths.

Where the 2 per cent emulsion was used, the tabulated results show but one case where a colony grew. This was after the 15 seconds exposure. Where the  $1\frac{1}{2}$  per cent emulsion was employed 3 such colonies were found, but only 1 was found in the case of the 1 per cent emulsion. Where the emulsion was of  $\frac{1}{2}$  per cent strength, 5 such colonies appeared after each were in the same dish. But in all the series where the time of exposure was 5 minutes or more not a single colony developed. From the laboratory experiment the author concludes that creolin is a true disinfectant, and that most favorable results are to be expected where the germs are few and the temperature comparatively high. To test the effect of creolin on the tissues, the author kept one hand immersed in undiluted creolin for 5 minutes, with the result that on the following day there was scarcely any perceptible effect. The small cost of the substance as well as its effectiveness makes creolin one of the best disinfectants and antiseptics for general use.

**The function of the white blood corpuscles,** F. FRIEDENTHAL (*Biol. Centbl.*, 17 (1897) No. 19, pp. 705-718).—The author reviews the literature relative to the subject, and gathering up the threads of his argument concludes that the white blood corpuscles serve an important rôle in the coagulation of the blood in the body, as scavengers in disease, attacking and removing foreign bodies, large and small. In animals with metamorphoses they aid in breaking down the old and building up the new tissues.

**An epidemic of botulism,** DINEUR (*Bul. Soc. Belge. Micros.*, 23 (1897), No. 4-6, pp. 45-66).—It is recorded that on December 5, 1896, there occurred at Antwerp an epidemic of botulism which attacked 76 out of 153 men, 19 of whom were taken to a hospital. Medical inquiry brought out the fact that the men had eaten sausages. The meat of the sausages was superficially examined, and as usual in cases of meat poisoning no apparent evidence of anything deleterious found. A chemical examination brought to light a ptomaine, but in quantities too small to be followed by noticeable results when injected into animals. Injections of fragments of the sausage into a mouse, however, produced death, and an inoculation of another mouse with cultures made from the blood of the first resulted similarly, the animal dying at the end of 22 hours. A microscopic examination of the sausage brought to light numbers of a coli bacillus. A brief historical résumé of the subject of botulism is given. In concluding, the author says, besides what has already been mentioned, that it appears that the animal, the flesh of which had been used in making the sausage, must have been in a bad state of nutrition, but whether this state was of a morbid nature, toxic or otherwise, is undeterminable. The evil effects that followed eating the sausages it was found could be avoided by heating the sausages to a temperature of 100° C. for 5 minutes.

**Agglutination of bacillus typhosus by chemical substances,** E. MALVOZ (*Ann. Inst. Pasteur*, 11 (1897), No. 7, pp. 582-590).—From the author's experiments, it appears that agglutination of this bacillus may be produced by formalin, corrosive sublimate, oxygenated water, and alcohol, when used on cultures. The concentration of the substances is an important matter with these substances, but with safranin and vesuvin only very dilute solutions are necessary, 1 per 1,000 being sufficient. A slight agglutinating action may be obtained with salicylic acid and permanganate of potash, while caustic soda and ammonia mixed with hard water have a strong agglutinating action, but not when mixed with distilled water. The action of these chemical substances was used by the author for the purpose of distinguishing the typhoid bacillus from *Bacillus coli communis*. Formalin was used. In the typhoid

cultures the bacilli were agglutinated into clumps while the coli bacilli were immobilized and isolated. From experiments made after washing off the outer layers of the bacteria, it appears that the agglutination phenomena are confined to the ciliated envelope.

**Some parasitical diseases of sheep**, E. A. SMYTH and E. P. NILES (*Virginia Sta. Bul.* 64, pp. 55-65).—There are here described in a popular manner several intestinal worms (*Strougyllus contortus*, *Æsophagostomum columbianum*, *Tonia expansa*, *T. conenrus* (gid), *T. echinococcus*), and the diseases produced by them. Treatment, it is thought, should preferably be precautionary, since in late stages of the disease it is of little value. Curtis is followed in recommending turpentine with an addition of six parts of milk. There is also recommended the following mixture, which the author has used with good results: Powdered arca root, 3 drams; powdered artemisia, 1½ drams; sodium bicarbonate, 6 drams. This mixture is to be divided into 3 powders and 1 given to each sheep 10 or 12 hours apart. If given in late winter and early spring when the larvæ of *Æsophagostomum columbianum* are emerging from their nodules, and the treatment continued at intervals of once or twice a month and the sheep changed from time to time to fresh pastures, the worm may be entirely removed from a field in the course of a year or so.

The remedy regarded most effectual for tapeworms, which are more difficult subjects to deal with, is arca nut powdered 2 drams, and powdered male fern 1 oz., all to be given at one dose.

**Staphylococcus hæmorrhagicus**, E. KLEIN (*Brit. Med. Jour.*, 1897, No. 2, pp. 385-387; *abs. in Jour. Roy. Micros. Soc. [London]*, 1897, No. 5, p. 429).—A coccus isolated from a vascular eruption on the hands of persons who had been skinning sheep that had died of gargle a few days after lambing, is described as pathogenic to man and animals. It belongs to the same group as *Staphylococcus pyogenes aureus*, is 0.4 to 0.6  $\mu$  in diameter, and grows freely on ordinary media. Gelatin is slowly liquefied by it and milk coagulated in about a week. Alkaline broth is rendered turbid and an acid reaction given in from 2 to 4 days. A whitish growth is produced on agar and gelatin, which becomes yellow with age and increases the size. Cultures were virulent to guinea pigs and sheep and produced chiefly a hæmorrhagic œdema of the subcutaneous and muscular tissue and sanguinolent fluid in the peritoneal sac. On the other hand, inoculations of the agar culture that had proved fatal to sheep gave positive results.

**Diseases of sheep**, T. D. HINEBAUCH (*North Dakota Sta. Bul.* 28, pp. 176-184).—A reprint of Bulletin 3 of the station (E. S. R., 3, p. 619).

**Pseudo-tuberculosis hominis streptotricha**, S. FLEXNER (*Bul. Johns Hopkins Hospital*, 18 (1897), pp. 128, 129; *abs. in Jour. Roy. Micros. Soc. [London]*, 1897, No. 5, p. 430).—In the lungs of a negro who died with symptoms of tuberculosis was found a fungus, branching, often occurring in clumps, or in convoluted masses. No microbes resembling *Bacillus tuberculosis* were found. On account of the lesions in the lungs and peritoneum and of the intimate relation of the streptothrix to the pathological processes and also on account of the symptoms resembling *Phthisis florida*, the organism was given the name *Pseudo-tuberculosis hominis streptotricha*.

**European government measures for the eradication of tuberculosis in farm animals** (*Landtmannen*, 8 (1897), Nos. 12, pp. 159-164; 13, pp. 180-185; 20, pp. 278, 279.)

**Measures against bovine tuberculosis in Sweden** (*Landtmannen*, 8 (1897), No. 34, pp. 480, 481).

**Septicæmia of calves**, THOMASSEN (*Ann. Inst. Pasteur*, 11 (1897), pp. 523-540; *abs. in Jour. Roy. Micros. Soc. [London]*, 1897, No. 5, p. 427).—A new disease of calves which is associated with nephritis and urocystitis. It has a duration of 5 or 6 days and besides parenchymatous nephritis and cystitis is accompanied by an enlargement of the spleen. A bacillus resembling in appearance the bacillus of typhoid or *Bacillus coli communis* was isolated from the blood, peritoneal fluid, and various organs. From *Bacilli coli communis* it is to be distinguished by its moist-looking growth on

potato, its slow growth on gelatin, its great mobility, by its inability to ferment lactose and to coagulate milk, and by its producing little or no indol or carbonic acid, as well as by the absence of any disagreeable odor from peptone bouillon or from gelatin cultures. Its serum reaction distinguishes it from the typhoid germ. The agglutination of fat is much less strongly marked and of a different character.

**Plague bacillus**, M. OGATA (*Centbl. Bakt. u. Par., 1. Abt., 21 (1897), pp. 769-777; abs. in Jour. Roy. Micros. Soc. [London], 1897, No. 5, pp. 426, 427*).—As a result of the author's observations made on plague patients in Formosa, it appears that an organism is constantly found in plague corpses in the lymphatic glands of plague patients which reproduces in animals a disease very closely resembling the plague. The presence of the plague bacillus is not constant in the blood of the plague patients. It may be found in the urine and bile of plague corpses; it may be transported by the flea and mosquito; it is constantly found in the blood and viscera of rats, naturally or artificially infected with the plague, and fleas feeding upon such rats often contain virulent bacilli. In patients other bacilli may be also present. It is but little resistant to antiseptics.

**Preventive vaccination against blackleg**, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 20, pp. 2*).

**Directions for the use of blackleg vaccine**, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Circ. 21, pp. 8, figs. 2*).—The method of preparing the vaccine in the laboratory of this Bureau is described, as well as the method of using it, noting in the latter case what animals are to be vaccinated and the size of the dose to be injected. A reprint of Circular 20 of the Bureau is appended.

**Micrococcus ghadialii**, GHADIALI (*Brit. Med. Jour., 1897, No. 2, pp. 418-419; abs. in Jour. Roy. Micros. Soc. [London], 1897, No. 2, p. 428*).—The author has discovered a coccus which has the power of slowly destroying the microbe of enteric fever in water and milk and also to a slight extent in bouillon. *Bacillus coli communis* in water also seems to be destroyed by it. In the experiments the enteric microbes were acclimatized before inoculation with the micrococcus.

**The fate of the tetanus toxin**, A. MARIE (*Ann. Inst. Pasteur, 11 (1897), pp. 591-599*).—The fact that a tetanus toxin injected into a vein requires a dose 7 to 8 times greater to kill the animal than if injected under the skin the author explains by stating that this toxin is easily and effectively carried to the central nervous system along nerve paths. In the circulation the plasma of the blood and the blood cells very materially alter the poison. It may remain in the blood for some time.

**Aspergillus fumigatus on domestic animals, etc.**, A. LUCET (*De l'Aspergillus fumigatus chez les animaux domestiques et dans les œufs en incubation. Paris: Mendel, 1897, pp. 108, pls. 14*).

**Resorption of bacteria after local infection**, J. HALBAN (*Sitzber. Math. Naturw. Cl. Akad. Wiss. [Vienna], 105 (1896), pp. 349-452, pls. 2*).—From experiments the author is able to say that the time required for different species of bacteria to reach the nearest lymphatic glands from the spot of inoculation varies with the bactericidal power of the alexin, being slower when that power is strong and quicker when it is weak. The time required to reach the blood is very variable. It was ascertained that an infection of a bleeding wound may remain local for about 2½ hours in the case of anthrax.

**Excretion of bacteria by the animal body**, F. J. COTTON (*Sitzber. Math. Naturw. Cl. Akad. Wiss. [Vienna], 105 (1896), pp. 453-512; abs. Jour. Roy. Micros. Soc. [London], 1897, No. 5, p. 426*).—Employing rabbits, the author made a series of experiments to ascertain the conditions under which and the time and in what quantity bacteria are excreted in the bile and in the intestine after intravenous injection. *Bacillus anthracis*, *B. subtilis*, *B. prodigiosus*, *B. pneumoniae*, *Staphylococcus aureus*, and *Diplococcus pneumoniae* were employed. From the results it is concluded that certain bacteria when present in large numbers in the blood may be excreted by the bile without perceptible changes taking place in the liver or bile ducts, but that almost necessarily large numbers of bacteria in the bile is associated with pathological changes.

Further, the presence of bacteria in the intestine and in the urine is almost certain evidence of pathological changes in the urinary tract or intestine.

**Empiricism or science: Anæsthetics, 1847 to 1897,** D. W. BUXTON (*Lancet* [London], 2 (1897), No. 3874, pp. 1369-1376).—A lecture delivered before the Society of Anæsthetists, November 18, 1897. It deals almost wholly with chloroform, the history of its use, its action, and the explanations that have been offered for the latter. It is stated that it can not be said that mortality as a whole has decreased since the beginning of the use of chloroform. Fewer mistakes would be made if only experienced persons were called upon to use the anæsthetic. Experienced men will use with safety the rudest means with impunity; but to allow the inexperienced to use such means is to court disaster.

## TECHNOLOGY.

**The sweet potato as a starch producer,** F. S. SHIVER (*South Carolina Sta. Bul.* 28, pp. 15).—Analyses of 4 samples of sweet potatoes made in the spring of 1894 showed the water content to range from 55.93 to 67.62 per cent, and the starch from 16.93 to 29.58 per cent. Analyses are given of 3 samples of sweet potatoes sent to the station and of 7 varieties grown at the station. The 7 varieties averaged 64.42 per cent of water and 26.31 per cent of starch.

“In connection with these analyses it is to be remarked that the season during which these tubers were grown was remarkably dry, and this in a measure accounts for the low percentage of water and the comparatively high percentage of starch.”

Calculated to a water content of 70 per cent, the average starch content was about 22 per cent.

Complete fodder analyses are also given of the 7 varieties grown at the station, including determinations of the cane sugar and glucose.

The value of the sweet potato as a starch producer is discussed and calculations are given showing that with a yield of 12,000 lbs. of sweet potatoes per acre the yield of starch would be about 2,640 lbs., about twice as much as the calculated yield from an acre of corn.

Analyses with reference to fertilizing ingredients are given of a number of samples of sweet potatoes, and on the basis of these analyses manuring of sweet potatoes is discussed. It is calculated that a crop of 200 bu. of sweet potatoes per acre would remove 27.36 lbs. of nitrogen, 10.2 lbs. of phosphoric acid, and 65.52 lbs. of potash, provided the vines were left on the land.

It is mentioned that the storage of sweet potatoes has received attention at the station and “it was found that among a great many materials tried cotton-seed hulls and dry sand gave the best results.”

In an introductory note M. B. Hardin states that the mechanical separation of the starch in 1 sample showed 20.61 per cent as compared with the analytical result of 22.82, and 19.96 per cent in another sample as compared with the analytical result of 21.74 per cent of starch. The starch separated mechanically was found to contain 96 per cent of starch.

Desiccation and other industrial applications of potatoes, A. OEHRE (*Aarsber. Offent. Foranst. Landbr. Fremme*, 1896, pp. 391-396).

Concerning *Saccharomyces zopfi* in sugar manufacture, etc., A. ARTARI (*Abhandl. Naturf. Gesell. Halle*, 1897, pp. 22, figs. 8).

The principles and practice of brewing, W. J. SYKES (London: Charles Griffin & Co., Ltd., 1897; rev. in *Analyst*, 22 (1897), Dec., p. 335).

Composition of different varieties of grapes and of different kinds of Sicilian wines in the year 1893, V. OLIVERI (*Atti. Staz. Chim. Agr. Sper. Palermo, Rap.* 1893-95, pp. 29, 30).

On the use of pure cultures of yeast in wine making, J. BEHRENS (*Centbl. Bakt. u. Par.*, 2. Abt., 3 (1897), Nos. 13-14, pp. 354-369; 15-16, pp. 415-423; 17-18, pp. 486-491).—An historical review of the subject.

On the making of wine from small berries, J. SEBELIEN (*Norsk Landmansblad*, 16 (1897), No. 31, pp. 348-350).

Raisin wine, P. CAZENEUVE (*Ann. Soc. Agr. Sci. et Ind. Lyon*, 7. ser., 4 (1896), pp. 333-355).

Grape wine and its substitutes, J. GRAFTIAN (*Bul. Agr. [Brussels]*, 13 (1897), No. 3, pp. 186-234).—The article discusses processes of manufacture, etc., and gives much general information.

Influence of coloring matters on the fermentation of highly colored red wines, P. CARLES and G. NIVIÈRES (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 12, pp. 452, 453).

On the formation of ammonia in wine, A. MÜNTZ and E. ROUSSEAU (*Bul. [Min. Agr. France]*, 16 (1897), p. 11).

Concerning the regulation of temperature during wine fermentation, E. O. MEINECKE (*Weinbau u. Weinhandel*, 1897, No. 15-16, pp. 129-139).

Recent studies on vinification and on the refrigeration of musts, A. MÜNTZ and E. ROUSSEAU (*Ann. Sci. Agron.*, 1897, I, No. 3, pp. 374-399, fig. 1).

The progress of vinification in Aude, L. SEMICHON (*Ann. Sci. Agron.*, 1897, I, No. 3, pp. 321-373).

On "casse des vins," a new explanation based on the rôle of iron, H. LAGATU (*Compt. Rend. Acad. Sci. Paris*, 124 (1897), No. 25, pp. 1461, 1462).

On the absorption of oxygen in "casse du vin," J. LABORDE (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 4, pp. 248-250).

Apropos of hydromel, R. PINCOT, (*L'Apiculteur*, 41 (1897), No. 2, pp. 60-62).—As an aid to fermentation dry raisins and tartaric acid are used. The latter is thought to be necessary with dry raisins, but not with fresh, since these have some acid of their own. The tartaric acid is added to the malt of honey and water at the rate of 60 gm. per hectoliter. A temperature of 25 to 28° C. is sufficient.

A study of the natural ferment of hydromel, E. KAYSER and E. BOULLANGER (*L'Apiculteur*, 41 (1897), No. 9, pp. 350-357).—The preparation of hydromel, a fermented beverage from surplus honey, is described and analyses of 9 samples are given and discussed. The production of hydromel is said to be quite difficult, the best conditions of fermentation not being well understood. These conditions are discussed in the light of data collected from a number of makers, and some suggestions are made as to the addition of foreign substances to influence the fermentation.

Vegetable fats and oils, L. E. ANDES (*Vegetabilische Fette und Oele*. Vienna, Pest, and Leipzig: H. Hartleben, pp. 189, figs. 94; abs. in *Ztschr. Nahr. Untersuch. u. Hyg.*, 10 (1896), p. 192).

## AGRICULTURAL ENGINEERING.

A study of waters for irrigation; the irrigation plant, G. L. HOLTER and J. FIELDS (*Oklahoma Sta. Bul.* 29, pp. 11).—Analyses with reference to mineral constituents are reported of 11 samples of river water,

12 samples of well water, and 3 samples of pond water. From these analyses the amounts of white and black alkali per 100,000 lbs. and per acre-inch are calculated and the adaptability of the different waters to irrigation purposes is discussed. Various suggestions are made regarding the construction of an irrigation plant, including dimensions of the reservoir and the capacity of pumps and windmills. Analyses with reference to sanitary condition of 12 samples of water are appended.

**The forces which operate to destroy roads, with notes on road stones and problems therewith connected,** C. L. WHITTLE (*U. S. Dept. Agr., Office of Road Inquiry Circ. 29, pp. 14, pls. 1*).

“Other things being equal, the endurance of a roadbed depends upon the qualities of the stone used, assuming the road to be properly constructed and adequately drained. A road is subject to attack and consequent loss of material in part by reason of the composition of the road metal of which it is composed. The means of attack brought to bear upon the surface of a road, in the order of their importance, are physical, dynamical, and chemical.

“The physical agencies are (1) the disrupting effects of frost, both on the integrity of the roadbed as a whole and on the individual rock fragments and minerals; (2) the transporting power of water in gulying the road, in washing particles of sand and clay to the side drains and ditches, and the sorting action of water whereby the winds are given better access to the finer and lighter parts of the products of road wear; (3) the transporting power of the winds; (4) the attrition and weakening effect of falling rain; (5) gravity.

“The dynamical agencies are (1) friction, which results from the grinding action of one fragment of rock against another under the action of carriage tires and the feet of animals; (2) the impact resulting from the same causes; (3) the disrupting effect of roots.

“The chemical agencies are (1) decomposition, shown, for example, by the disintegration of the feldspar-bearing rocks whereby the feldspars and other minerals are converted into clay, quartz, calcite, etc.; (2) solution, or the power possessed by surface waters impregnated with acids to dissolve most rocks and the products of decomposition of others and carry them away.”

These different agencies are discussed in detail, as well as the essential qualities of road stones, the relation of decomposition to cementation, and the effect of moisture on a roadway. The structure of different classes of stone, including diorite, diabase, marble, and granite, are shown in plates made from microphotographs of sections of the stone. The planting of trees along highways is advocated and the chestnut is especially recommended for this purpose.

**Irrigation in New Jersey,** E. B. VOORHEES (*New Jersey Stat. Rpt. 1896, pp. 185-232, pls. 5*).—This article forms part of Bulletin 36 of this Office (E. S. R., 9, p. 97).

**Trials of farm machinery,** W. MÖLSE (*Biet [Helsingfors], 18 (1897), No. 5-6, pp. 141-144*).—The trials were conducted under the auspices of the Nyland and Tavastehus County Agricultural Society (Finland) and included tests of mowing machines (7) and planters and cultivators (10).

**Trial stations for agricultural machinery and apparatus** (*Landtmannen, 8 (1897), No. 33, pp. 457-460*).—Contains regulations for the trial stations for testing agricultural machinery and apparatus recently established at the agricultural and dairy institutes of Ultuna and Alnarp (Sweden).

**Agricultural machinery in Germany and England,** M. LANGBALLE (*Aarsber. Offent. Foranst. Landbr. Fremme, 1896, pp. 329-341*).

**Silage presses**, J. J. MORTENSEN-BARRIT (*Landtmannen*, 8 (1897), No. 35, pp. 493, 494).

**Highway repairing**, J. O. SANFORD and E. G. HARRISON (*U. S. Dept. Agr., Office of Road Inquiry Circ. 24*, pp. 12).—This includes accounts of the practical advantages of the daily care of country roads and notes on the improved roads at Canandaigua, New York, as well as opinions of leading citizens in the States of Wisconsin, Iowa, and Indiana relating to the working of a cash tax in those States.

**Going in debt for good roads**, THAYER (*U. S. Dept. Agr., Office of Road Inquiry Circ. 26*, pp. 6).—An address delivered before the Iowa Bankers' Association at Council Bluffs May 24, 1893.

**Addresses on road improvement in Maine, New York, North Carolina, and Illinois**, R. STONE (*U. S. Dept. Agr., Office of Road Inquiry Circ. 28*, pp. 26).—The text of addresses delivered before the State Board of Agriculture, Augusta, Maine, January 21, 1897, and before the General Assembly of North Carolina, Raleigh, North Carolina, February 5, 1897; remarks before the committees of Senate and Assembly at Albany, New York, February 25, 1897, and at the Good Roads Banquet of the League of American Wheelmen, Albany, New York, February 11, 1897; and a letter to the Illinois Farmers' Institute.

### STATISTICS—MISCELLANEOUS.

**Reports of director and treasurer of New Jersey Stations, 1896** (*New Jersey Stat. Rpt. 1896*, pp. XXI, 1-15).—Brief review of the work of the departments of chemistry, horticulture, dairy husbandry, biology, botany, and entomology during the year, and a financial report of the State Station for the year ending October 31, 1896, and of the College Station for the fiscal year ending June 30, 1896.

**Annual Report of Oregon Station for 1897** (*Oregon Sta. Rpt. 1897*, pp. 8-31).—This includes reports by the director and heads of departments reviewing the work of the year and offering suggestions as to future work; a financial report for the fiscal year ending June 30, 1897, and a subject list of the bulletins (Nos. 1 to 47 inclusive) published since the organization of the station.

**Annual Reports of the Department of Agriculture for 1897** (*U. S. Dept. Agr., Rpt. 1897*, pp. 226).—Executive reports.

**Indiana agricultural statistics for 1895** (*Indiana State Bd. Agr., 1896*, pp. 186-235).

**Iowa agricultural statistics for 1896** (*Iowa State Agr. Soc. Rpt. 1896*, pp. 145-174, maps 22).—A review of the crop season, with data showing the total acreage and the average yield per acre of various farm crops and the kinds, number, and distribution of farm animals in each county of the State.

**Agricultural statistics, Ireland, 1897** (*Dublin: Alex. Thom & Co., 1897*, pp. 39).—General abstracts showing the acreage under crops and the number and description of live stock in each county and province, with notes on crop conditions during the last week in July, 1897.

**Crop and live stock statistics, 1897** (*Kansas State Bd. Agr. Rpt. 1897*, pp. 225-282).—The tabulated data here given show the acreage, value, and yield per acre by counties of farm crops grown in the State; the number, value, and kinds of live stock, and the amount and value of their products; the yields and value of orchard and small fruits; the number of stands of bees, and the amount and value of honey and wax produced; and the acreage of newly planted forests and the kinds of trees planted.

**Report on crops, live stock, etc., in Manitoba** (*Manitoba Dept. Agr. and Immigration Bul. 54*, pp. 18).—Statistics on the acreage and yield of wheat, oats, barley, flax, rye, peas, potatoes, and roots; the number of live stock in the province and the number exported; production and price of dairy products, with general remarks by correspondents on crop and farm conditions.

**Ohio crop and live stock statistics for 1896** (*Ohio State Bd. Agr. Rpt. 1897*, pp. 19-74).

**Statistics of Ontario** (*Ontario Bureau Ind. Bul. 63*, pp. 24).—Statistics of the several staple farm, orchard, and garden crops, showing the total area, product, and market value of the crops for 1896 and for the 4 years preceding, and the averages for 5, 10, and 15 year periods; the ratio of crops per 1,000 acres cleared land; the number, kinds, and value of live stock for the years 1892 to 1896; wages of farm laborers for 1895 and 1896 and the average for the years 1882-'96; output and value of cheese factories and creameries; value of farm property; number and amount of chattel mortgages; the world's wheat crop for the years 1894-'97; and the area and yield of field crops of Ontario for 1897.

**Crops and live stock in Ontario** (*Ontario Bureau Ind. Bul. 64*, pp. 32).—Final estimates of yield of crops in Ontario for the year 1897, with statistics of live stock for the years 1894 to 1897, and extracts from remarks by correspondents on miscellaneous farm topics. The yields of crops as given are based on actual threshing returns reported by nearly 4,000 correspondents.

**Seventh annual report of the agricultural bureau of the department of agriculture, insurance statistics, and history, 1893-'94** (*Texas Agr. Bureau Rpt. 1893-'94*, pp. 600).—This includes agricultural and general statistics of each county in the State for the year 1893-'94.

**Virginia agricultural statistics for 1896** (*Virginia State Bd. Agr. Rpt. 1896*, pp. 38-55).—Crop reports and statistics on acreage and yield of farm crops grown in Virginia in 1896.

**Seventh annual report of farmers' institutes held in Ohio during the winter of 1896-'97** (*Ohio State Bd. Agr. Rpt. 1896*, pp. 275-631).—Includes a statement of the receipts and disbursements of the Ohio State Board of Agriculture on account of farmers' institutes for the season of 1896-'97; tabulated data showing the places where held, dates, attendance, etc., of the different institutes; a list of the lectures and their subjects; reprints of 58 miscellaneous papers; and the proceedings of the annual institute held at Columbus, with the full text of the papers read. The text of the Ohio State law governing farmers' institute societies and the rules of the State Board of Agriculture regulating their management are appended. In all 212 two-day institutes were held during the winter season. The attendance varied from 50 to 1,000, with an average of 353 and a total attendance of 76,815.

**Proceedings of the ninth general meeting of the Association of Agricultural Experiment Stations in the German Empire at Wiesbaden, September 18 and 19, 1896** (*Landw. Vers. Stat., 49 (1897), No. 1-2*, pp. 1-82).—An account of this meeting has already been given (*E. S. R.*, 8, p. 447).

**Agricultural extension work: Sketch of its origin and progress** (*New York Cornell Sta. Bul. 137*, pp. 325-333).—Previous accounts of the extension work of the College of Agriculture of Cornell University have been reported in Bulletins 110 and 122 of the station (*E. S. R.*, 8, pp. 135, 790).

The present bulletin gives a review of the university extension work since its inception in western New York in 1893, and of the State legislation since affecting it; points out the purpose and general scope of the work and gives an account of its growth; and discusses the results secured by each of the different methods for the dissemination of agricultural knowledge thus far tried. At the present time there are enrolled in this university extension work 15,000 pupils and 10,000 teachers of the public schools and 1,600 young farmers.

**Cost of hauling farm products to market or to shipping points in European countries** (*U. S. Dept. Agr., Office of Road Inquiry Circ. 27*, pp. 12).—This circular gives the more important consular reports on this subject "received through the Department of State in response to the request of the Secretary of Agriculture for such information and in reply to circulars issued to the United States consuls by the Department of State." The countries represented are Belgium, England, France, Germany, Italy, and Switzerland.

## NOTES.

MASSACHUSETTS COLLEGE AND STATION.—During the past year the greenhouse of the station has been materially altered. A new hot-water heater has been put in, and 3 ranges of houses have been built to be heated at different temperatures. These consist of a lean-to 25 by 25 ft. with a southern exposure and heated for cucumbers and tomatoes. The beds in this house are  $2\frac{1}{2}$  by 18 ft. and run East and West in tiers. There is also a lettuce house 12 by 40 ft. with earth beds, and a propagating house 12 by 18 ft. for general experimental purposes where a high temperature is not required. These houses have all been constructed with a view to getting the most uniform and normal conditions for physiological experiments. The appropriation for these changes was \$1,500. In the horticultural department of the college and station an appropriation of \$1,000 was made to remodel 2 greenhouses.

NEBRASKA UNIVERSITY AND STATION.—The following changes have been made in the governing board: E. Von Forell, of Kearney, has been appointed, *vice* C. W. Kaley, and George F. Kenower, of Wisner, *vice* E. A. Hadley.

NEW YORK STATE STATION.—H. A. Harding, of the University of Wisconsin, has been elected dairy bacteriologist of the station. He will spend the present year in study in this country and Europe and will assume his duties on January 1, 1899. George A. Smith, former director of farmers' institutes in New York and at present one of the dairy experts of the New York State Department of Agriculture, has been elected dairy expert at the station. It is expected that the new biological and dairy building will be ready for occupancy in the early summer of 1898.

RHODE ISLAND COLLEGE.—A special winter course of study and training in poultry culture has been successfully completed. The course lasted 4 weeks, beginning January 10, 1898. Instruction was given in zoology, the origin and breeds of fowls, principles of breeding and their application, care and management of fowls, feeding, diseases, construction of poultry buildings and appliances, drainage, records and accounts, etc. The plan was to devote the forenoons to lectures and class-room work; the afternoons to laboratory work and to practice in the carpenter shop, incubator house, and brooder house, and to the management, care, and feeding of fowls; the evenings to study, to meetings for discussion, etc. On Saturdays excursions were made to different poultry farms, markets, cold-storage establishments, etc. Special public lectures were planned. No entrance examinations were required, but examinations were held during and at the close of the course, on the basis of which certificates were awarded according to merit. The school was attended by 8 regular and as many more irregular students. Two of the regular attendants were women. Besides Rhode Island, pupils came from New York, New Jersey, and Massachusetts.

TEXAS COLLEGE.—L. S. Ross, president of the State Agricultural and Mechanical College of Texas, died January 3, 1898.

UTAH COLLEGE AND STATION.—U. P. Hedrick, formerly of the Oregon College and Station, has been elected horticulturist and botanist of the college and station, to succeed F. C. Scars, resigned. The latter has become director of the School of Horticulture at Wolfville, Nova Scotia.

# EXPERIMENT STATION RECORD,

EDITED BY

A. C. TRUE, PH. D., *Director,*

AND

E. W. ALLEN, PH. D., Assistant Director—Chemistry, Dairy Farming, and Dairying.

Editorial notes: Statistics of the colleges of agriculture and mechanic arts and the experiment stations.....	701
Agricultural education and research in the Scandinavian countries and Finland, F. W. Woll.....	703
Recent work in agricultural science.....	720
Notes.....	800

### SUBJECT LIST OF ABSTRACTS.

#### CHEMISTRY.

The principal amid of sugar cane, E. S. Shorey.....	720
Toxalbumoses which coagulate blood, M. Elfstrand.....	720
Report of the chemist, R. De Roode.....	721
Report of the chemist, W. B. Hardin.....	724
The determination of nitrogen in organic substances by the Kjeldahl-Wilfarth method, R. de Böhtlingk.....	721
The determination of the total volatile fatty acids in butter, E. Wrampelmeyer.....	722
The detection of foreign fats in lard and butter, C. B. Cochran.....	722

#### BOTANY.

Report of the botanist and microscopist for 1891, C. F. Millspaugh.....	726
Report of the botanist, H. L. Bolley.....	726
Experimental investigations on the assimilation of ammoniacal and nitric nitro- gen by the higher plants, E. Laurent, E. Marchal, and E. Carpiaux.....	724

	Page.
On the absorption of organic matter by roots, J. Laurent .....	724
Some considerations upon the functions of stomata, C. E. Bessey.....	725
On the formation of fats in seeds and fruits, C. Gerber.....	725
Influence of various substances added to water cultures and of oxygen on the formation of chlorophyll, W. Palladin .....	725
Plant growth with or without argon, T. Schlössing, jr.....	725
Report upon preliminary experiments with the Röntgen rays on plants, G. F. Atkinson .....	725

## ZOOLOGY.

Some common birds in their relation to agriculture, F. E. L. Beal.....	727
--	-----

## METEOROLOGY.

Meteorological observations, J. E. Ostrander, J. L. Bartlett, and A. C. Monahan.....	729
Meteorological observations, 1896, C. S. Phelps .....	729
Meteorological observations, W. B. Alwood .....	731
Report of the meteorologist, G. D. Swezey and G. A. Loveland .....	730
Temperature and rainfall, E. F. Ladd .....	731
The weather.....	731

## WATER—SOILS.

Artesian well waters, E. F. Ladd.....	738
Experiments on the nitrification of the nitrogenous matter of the soil and of various nitrogenous fertilizers, P. Bonâme.....	731
The mechanics of soil moisture, L. J. Briggs .....	732
Investigations on the temperature conditions of different kinds of soil, E. Wollny .....	734
Investigations on the influence of frosts on the temperature conditions of soils with different salt contents, R. Ulrich.....	735
Soil moisture, E. F. Ladd.....	735
Protection and improvement of worn soils, J. S. Newman.....	735
The value of plant roots as tillers of the soil, R. H. Elliot .....	736
The fruit soils of Oregon, G. W. Shaw .....	737
Report of the geologist, E. H. Barbour.....	737
A reconnoissance in southeastern Washington, I. C. Russell.....	737

## FERTILIZERS.

Concerning fertilizers and manures, G. L. Teller.....	740
The preservation of nitrogen as well as the transformation of different forms of nitrogen in barnyard manure, W. Schneidewind .....	738
Commercial fertilizers and chemicals, R. T. Nesbitt and G. F. Payne .....	739
Fertilizer inspection, C. D. Woods and J. M. Bartlett.....	739

## FIELD CROPS.

Report of the agriculturist, J. H. Shepperd.....	741
Report of the agriculturist, D. D. Johnson .....	748
Influence of various amounts of nitrogen on the development of barley, D. N. Pryanishnikov and S. M. Kouznezov .....	741
Soil inoculation for leguminous plants, J. F. Duggar .....	743
The color of rye grains, N. Westermeier .....	744
The soy bean as a forage crop, T. A. Williams .....	745
Mineral constituents of the sugar-cane crop, P. Bonâme.....	745
Field experiments with fertilizers, C. S. Phelps.....	746

	Page.
Field experiments with fertilizers, C. E. Thorne, J. F. Hickman, and W. J. Green .....	747
Methods of curing tobacco, M. Whitney .....	748
Tests of fertilizers on wheat, D. O. Nourse .....	747

## HORTICULTURE.

Asparagus culture, R. B. Handy .....	749
Analyses of sweet potatoes, W. B. Hardin .....	754
Department of horticulture and forestry, C. B. Waldron .....	749
Report of the horticulturist, J. F. C. Du Pre .....	754
Report upon fruit trees, plants, etc., W. W. Brown .....	755
Grafting the apple, S. C. Mason and I. Jones .....	750
Is there permanent prosperity for the Oregon prune industry? H. B. Miller..	755

# EXPERIMENT STATION RECORD.

VOL. IX.

No. 8.

A compilation of statistics relative to the land-grant colleges and the agricultural experiment stations in this country has just been completed by this Office. These statistics illustrate the magnitude of the enterprises for education in agriculture and the mechanic arts and for experimentation and research in agriculture which are fostered by the Federal and State Governments. The statistics for the colleges are much more complete than any which have hitherto been collected. Owing to the complex organization of many of the institutions, it has been found impracticable to give exactly comparable statistics in all cases, and in some instances it was impossible to obtain complete data.

There are at present 64 institutions receiving the benefits of the acts of Congress of July 2, 1862, and August 30, 1890. Sixty-one of these institutions maintain courses of instruction in agriculture. The aggregate value of the permanent funds and equipment of the land-grant colleges and universities in 1897 is estimated to be \$51,274,546.60, classified as follows: Land-grant fund of 1862, \$10,243,132.82; other land-grant funds, \$1,319,133.41; other permanent funds, \$8,567,619.27; land grant of 1862 still unsold, \$2,399,383.70; farms and grounds owned by the institutions, \$5,564,488.91; buildings, \$13,994,205.64; apparatus, \$1,533,282.38; machinery, \$1,048,503.31; libraries, \$1,425,004.88, and miscellaneous equipment, \$1,935,290.51. The total number of acres of land granted to the States under the act of 1862 was 8,978,960, of which 1,066,519 acres are still unsold.

The income of these institutions in 1897, exclusive of the funds received from the United States for agricultural experiment stations, was as follows: Interest on land grant of 1862, \$609,992.64; interest on other funds, \$574,120.08; United States appropriation under act of 1890, \$1,009,097.07; State appropriation (annual or regular), \$1,477,170.94; State appropriation (occasional), \$318,901.07; tuition fees, \$480,375.45; incidental fees, \$50,555.98; miscellaneous, \$708,971.47; total, \$5,178,580.82. The value of the additions made in 1897 to the permanent endowment and equipment of these institutions is estimated at \$1,370,518.71.

In 1897 the faculties of the colleges of agriculture and mechanic arts numbered 1,520 persons, of whom 240 were for preparatory classes and 1,372 for collegiate and special classes. In other departments of the

institutions the faculties aggregated 791, making a grand total of 2,311 persons in the faculties of the land-grant institutions.

The students in 1897 numbered 28,885. Of these, 3,930 were in agriculture, 2,441 in mechanical engineering, 1,375 in civil engineering, 1,166 in electrical engineering, 575 in mining engineering, 393 in architecture, 1,051 in household economy, 354 in veterinary science, and 8,295 in military tactics. The graduates of these institutions in 1897 numbered 1,687, and since the organization of these institutions 25,737. The average age of graduates in 1897 was 21.9 years.

All of the States and Territories now have agricultural experiment stations receiving the benefits of the Hatch Act. Alaska alone has no experiment station, but a preliminary investigation regarding the feasibility of conducting agricultural experiments in Alaska was made by this Department the past year, and funds have been appropriated by Congress for inaugurating experiments there the coming season. In four of the States separate stations are maintained wholly or in part by State funds, and in Louisiana a station for sugar experiments is maintained partly by funds contributed by sugar planters. Excluding the branch stations, there are 54 stations, 52 of which receive the appropriation provided by the Hatch Act.

The total income of the stations during 1897 was \$1,129,832.99, of which \$719,993.47 was received from the National Government, the remaining \$409,839.52 coming from the following sources: State governments, \$287,176.35; individuals and communities, \$5,553.88; fees for analyses of fertilizers, \$37,265.26; sales of farm products, \$64,437.83; and miscellaneous, \$16,906.20. In addition to this, the Office of Experiment Stations had an appropriation of \$35,000 for the past fiscal year, including \$5,000 for the Alaskan investigation. The value of additions to equipment of the stations in 1897 is estimated as follows: Buildings, \$74,830.99; libraries, \$12,993.25; apparatus, \$21,149.73; farm implements, \$13,178.25; live stock, \$14,733.07; miscellaneous, \$7,714.08; total, \$143,599.38.

The stations employ 628 persons in the work of administration and research. These are classified as follows: Directors, 67; chemists, 134; agriculturists, 66; horticulturists, 71; farm foremen, 38; dairymen, 19; botanists, 47; entomologists, 48; veterinarians, 30; meteorologists, 18; biologists, 8; physicists, 9; geologists, 6; mycologists and bacteriologists, 21; irrigation engineers, 6; in charge of substations, 11; secretaries and treasurers, 70; librarians, 9; and clerks, 38. There are also 30 persons classified under the head of "miscellaneous," including superintendents of gardens, grounds, and buildings, apiarists, herdsmen, etc. Two hundred and eighty-five station officers do more or less teaching in the colleges with which the stations are connected.

In 1897 the stations published 54 annual reports and 324 bulletins. Aside from these, a number of the stations issued press bulletins, which were widely reproduced in the agricultural and county papers. The station mailing lists now aggregate over a half million names.

# AGRICULTURAL EDUCATION AND RESEARCH IN THE SCANDINAVIAN COUNTRIES AND FINLAND.<sup>1</sup>

F. W. WOLL,

*Assistant Professor of Agricultural Chemistry, University of Wisconsin.*

## HIGHER AGRICULTURAL INSTRUCTION.

The institutions offering higher instruction in agriculture in the Scandinavian countries and Finland are 5 in number: Aas Higher Agricultural School, Aas, Norway (established 1859); Ultuna Agricultural Institute, Ultuna, Sweden (established 1849); Alnarp Agricultural and Dairy Institute, Aakarp, Sweden (established 1862); Royal Veterinary and Agricultural College, Copenhagen, Denmark (established 1773); and Mustiala Agricultural and Dairy Institute, Mustiala, Finland (established 1840).

All of these institutions are comparatively old, with traditions of their own, and plans of instruction suited to the particular conditions under which each institution is working. It is but natural, however, that the educational system followed at the different colleges should have been repeatedly modified and further developed in the course of time during their existence.

*Higher Agricultural School at Aas.*—At the present time the institutions of Norway and Finland, Aas and Mustiala, respectively, are under reorganization. In the former country the commission which has had the subject under consideration has prepared an elaborate report and recommended the organization of an agricultural college at Aas, the purpose of which shall be "to impart instruction based on a scientific foundation for the education of farmers, foresters, gardeners, allotment officers (surveyors), and dairymen, and to promote scientific research in the branches embraced by the college." The course is planned to last two years for all students except those in forestry, whose course lasts three years. The first year's studies are the same for all students, and during the second year classes are formed in agriculture, allotment, horticulture, dairying, and forestry. The buildings and increased instructional facilities rendered necessary by the reorganization will be provided for by a special appropriation of 682,000 crowns (\$185,000), of which sum 250,000 crowns, or nearly \$100,000, is for a new agricultural hall. The new college is planned to accommodate 120 to 150 students. The faculty will consist of a director, 11 pro-

<sup>1</sup> Continued from page 616.

fessors, and 6 instructors (*docenter*). The bill for the reorganization of the college was reported favorably last year by the committee on agriculture of the Norwegian Parliament, and is expected to pass and become a law during the present session of the Parliament.<sup>1</sup>

During its existence the Aas Higher Agricultural School has been frequented by nearly 1,000 students, the large majority of whom have been or are at the present time farmers in Norway. The course of instruction given lasts 1 year and is theoretical only, being arranged on the plan of the elementary agricultural 2-years' course given at the same school. The school is open to all persons sending in their applications accompanied by a doctor's certificate of freedom from contagious disease. The tuition fee is 200 crowns (\$53.60) a year; students rooming and boarding at the school pay 400 crowns (\$107.20) in addition. The attendance at the school is at present about 35 students a year. Like all the higher agricultural educational institutions in the Scandinavian countries, Aas is supported by Government appropriations solely, aside from the farm sales. The budget for 1893-'94 was 112,265.34 crowns (\$30,342), about two-thirds of which was for instructional purposes and one-third for the farm. The latter portion was more than covered by the income from farm sales, amounting to very nearly 50,000 crowns (\$13,500).

*Mustiala Agricultural and Dairy Institute.*—This institution (fig. 3), which was established as an elementary agricultural school in 1840, was enlarged in 1845 by the addition of a department for the training of agricultural teachers and farm superintendents. This department has gradually grown in importance since 1865, and has of late years been the main feature of the institute. The faculty of the institute is made up of a director (Dr. Gosta Grotenfelt); *lektor* in chemistry and in botany; teachers in dairying, forestry, and veterinary science; "elementary teacher;" assistant chemist; and secretary and treasurer, 9 members in all. The attendance at the institute since its organization has been as follows:

*Attendance at Mustiala Agricultural and Dairy Institute, 1840-'95.*

	1840-'64.	1864-'81.	1881-'90.	1890-'95.	Total.
Agricultural department:					
Higher course.....		161	136	116	413
Elementary course.....	395	213	185	122	915

Higher course.....			31	31	62
Elementary course.....		114	15	16	145
Total.....	395	488	367	285	1,535

Students are admitted to the elementary course on similar conditions as to other Finnish elementary agricultural schools mentioned above. To the higher course, the agricultural institute proper, graduates of

<sup>1</sup>The law establishing the Agricultural College of Norway at Aas was passed May 22, 1897.

FIG. 3.—Agricultural and Dairy Institute at Mustiala, Finland.

the Finnish *lyceums* (corresponding to our high schools) and students holding a bachelor's degree from the State University at Helsingfors are admitted without examination, on presenting the required certificates from pastor and doctor as to age, moral character, general health, freedom from contagious disease, etc. Applicants having had at least a year's experience in practical farm work are given precedence in filling vacant places.

As in case of all Finnish educational institutions, the confusion of languages in Finland places the teachers at agricultural schools under peculiar difficulties. The Swedish-speaking population of Finland numbered 14.3 per cent in 1880, and the Finnish-speaking 85.2 per cent, the rest—less than 10,000—being made up of Russians, Germans, Laplanders, etc. Of the city population about 40 per cent are Swedish speaking. In the elementary schools located in the southwestern part of the country the instruction is given in Swedish, while in the other schools the Finnish language is used. In a few cases both Finnish and Swedish are used. Thus, at Mustiala, the professors, according to a Government decree, lecture in Swedish and Finnish in alternate years of the course, and they may therefore in one hour lecture to one class in Swedish and in the next hour to another class in Finnish.

For a number of years past there has been considerable discussion in Finland concerning the system of higher agricultural education. It has long been felt that the instruction at Mustiala under the conditions present—with the management of a 15,700 acre farm and of the higher and the elementary agricultural school alike in hands of the director of the institute—did not come up to what might reasonably be expected of a modern institution for the scientific training of young men in agriculture. The matter has been discussed by committees appointed by the Government and in the agricultural and daily press, and as an outcome a law has recently been passed providing 2 professorships at the Alexander University in Helsingfors, one in agricultural economics and agriculture, and the other in agricultural chemistry and agricultural physics, with an instructor (*adjunkt*) in botany and bacteriology, "in order to advance in this country scientific research and instruction in the subjects pertaining to agriculture." The advanced agricultural instruction will then be transferred to the State University, in connection with which an agricultural college will gradually be built up, and Mustiala will be reorganized as an intermediate agricultural school, with courses of instruction similar to those now offered at Kronoborg and Harjus.

*Higher agricultural instruction in Sweden.*—Turning our attention now to higher agricultural instruction in Sweden, we find here 2 well organized and equipped agricultural colleges, one each at Ultuna and Alnarp.

(1) Ultuna Agricultural College is the oldest Swedish agricultural college. It is located near Upsala, the university city, about 40 miles north of Stockholm. It has a faculty of 11 members, 4 so-called *lektorer*,

4 *adjunkter*, and 3 special teachers. There are about 50 students at the college. The course of instruction is arranged for 2 years, beginning November 1 and ending October 24, with a 3 weeks' vacation at Christmas and 7 weeks in summer time. The students generally hold a bachelor's degree, are graduates of Swedish technical institutions, or have similar qualifications. The instruction consists of lectures, laboratory work, "rounds," and excursions. During the junior year 635 to 675 lectures and 123 hours of laboratory work are given, and during the senior year 494 to 534 lectures, with 111 hours of laboratory work.

"Rounds" are made twice a week in the stock stables during the winter months by each class, under the direction, alternately, of the professors of animal husbandry and of veterinary science. Rounds in the creamery are made as suggested by the lectures in dairying, under the direction of the professor of dairying; and rounds in the barns and the fields are made occasionally during the winter, and regularly once a week with each class during the summer, under the direction of the professor of agriculture and economics. In all 6 or 8 geological excursions are made during the summer and 2 botanical excursions a week are made in the vicinity of the institute. Each summer an excursion, the plan of which is carefully laid a long time in advance, is made to estates at some, often considerable, distance from the institute. The expenses of these excursions are borne by the institute.

Two fellows (*stipendiater*) are appointed each year from the graduates having the best standing. They have a scholarship of 300 crowns (\$81) a year, with free board and room, and may be reappointed for a second year. They do not ordinarily take part in the instructional work in the institute, but are free to devote themselves to special study. Regular students pay a tuition fee of 175 crowns (\$47.30) and for board and room 500 crowns (\$135) a year; special students (*hospitanter*) pay 75 crowns (about \$20) a month. Four students, 2 in each class, are given scholarships.

The budget of the institute amounts to a little over \$20,000, two-thirds of which is covered by Government appropriations. The farm connected with the institute contains 1,549 acres, and is well provided with instructional facilities, laboratories, library, museum, and farm live stock. About 200 milch cows (largely Ayrshire blood), 30 working horses, and 66 swine are kept.

(2) Alnarp Agricultural and Dairy Institute (fig. 4) is located in the southern part of Sweden, in the fertile province of Skaane, only about 20 miles from Copenhagen.

As at Ultuna, the course of instruction lasts 2 years. Lectures and recitations are given as follows: *Junior year*—Inorganic and organic chemistry (60 and 40 hours, respectively), with laboratory practice (about 250 hours); physics and meteorology (40 hours); geology (35 hours); anatomy and physiology (30 hours), with dissections; zoology (6 hours), general botany (30 hours), mechanics and engineering (30 hours), surveying

(15 hours), bookkeeping (50 hours), forestry (33 hours), general horticulture (25 hours), farriery (30 hours), and cameralistics (15 hours). *Senior year*—Agricultural chemistry (56 hours), applied botany (45 hours), agriculture (147 hours), history and economics of agriculture (38 hours), animal husbandry (25 hours); cattle, sheep, swine, and poultry raising (40, 8, 10, and 4 hours, respectively); dairying (56 hours), horse raising and exterior of the horse (25 hours each), veterinary science (28 hours), fish culture (7 hours), engineering and architecture (54 hours).

The faculty consists of 13 members. The number of students during 1894 was 98, the attendance in the different courses being as follows:

Agricultural Institute:	Students.
Higher department (4 scholarships) .....	27
Elementary department (24 scholarships).....	44
Dairy Institute:	
Higher department (15 special students).....	21
Elementary department.....	6
Total .....	<u>98</u>

FIG. 4.—Main building, Alnarp Agricultural and Dairy Institute at Aakarp, Sweden.

Regular students pay 675 crowns (\$182.43) a year for tuition, room, and board. The incidental expenses, washing, light, and books, are about 160 crowns (\$43.24) per year. Special students pay at the rate of 75 crowns (\$20) a month, which includes charges for tuition, room, and board.

The Alnarp estate contains 1,390 acres of land, of which 735 acres are under cultivation, 103 acres are laid out in parks, yards, and roads, 25 acres are in orchards, and 267 acres are rented to tenant farmers. In

1896 160 acres (65 hectares) were planted to sugar beets. The gross receipts from the beet crops amount to about \$13,000 annually. The beets are sold to the beet-sugar factory adjoining the estate. The Government appropriation for the institute is 29,400 crowns (\$8,000) a year, and the budget about 60,000 crowns (\$17,000).

*Institutions for higher agricultural education in Denmark.*—Among these is the Royal Veterinary and Agricultural College of Copenhagen, the oldest and largest of its kind in the Scandinavian countries or Finland. The college was established by Dr. P. C. Abildgaard in 1773 as the Danish Veterinary School. It received State aid from the beginning and became in 1776 a State institution, the Royal Danish Veterinary School. The school was reorganized and enlarged in 1858, and its name changed to that given above.

A number of changes and improvements have been made in the organization and plan of instruction of the college, the latest regulations being issued in 1892. The college, as now organized, has 5 separate departments, viz, veterinary, agriculture, land inspection (surveying, corresponding to the proposed course in land allotment in Norway), horticulture, and forestry. In addition there are post-graduate courses for veterinarians and agricultural students, and also a school for farriers.

To be admitted as a regular student, the applicant must either have a bachelor's degree or have passed the special entrance examinations prescribed, including 3 foreign languages. Students in the veterinary department are also required to pass an examination in Latin. There is furthermore an opportunity to be admitted as a regular student by special permission of the Department of the Interior. Special students are admitted without entrance examinations and may receive diplomas on the completion of the full course of study in any department. They are, however, restricted from receiving any of the scholarships of the college. Students must be at least 16 years old on entering the college, but the average age is considerably higher, being over 20 years.

The courses of study offered in the different departments are comprehensive and thorough, being designed to give to the student a liberal technical training and a good knowledge of the scientific principles underlying agriculture and kindred professions. The full course in veterinary science lasts 4½ years, of which time the last half year is devoted largely to practical work, hospital service, meat control, etc. The course is divided into 3 divisions, the first division taking 1 year, the second division 2 years, the third division, part 1, 1 year, and part 2, one-half year. At the completion of the work of each division, or each part thereof, examinations are held in all studies taken.

The course in agriculture lasts 1½ years, and is divided into two divisions. In division 1 the following lectures and recitations are given: Chemical physics, mechanics and optics, meteorology, inorganic and organic chemistry, analytical chemistry, geology and geognosy,

soils, botany, biology, agricultural zoology, anatomy of farm animals, agricultural machinery; and laboratory or field work in chemistry, botany, horticulture, surveying, and drafting. In division 2 the lectures and recitations given are: Agricultural machinery (continued), plant culture, animal husbandry, dairying, farm bookkeeping, economics of agriculture, and plant pathology; and laboratory or field work in stock judging, agricultural chemistry, composition on agricultural topics.

The course in the department of land inspection is arranged in 3 divisions, of about  $1\frac{1}{2}$ ,  $1\frac{1}{4}$ , and 1 year, respectively, or  $3\frac{3}{4}$  years in all. The studies pursued are largely the general sciences, engineering, surveying, social economy, and general agriculture.

The course in horticulture requires  $2\frac{1}{8}$  years, and that in forestry  $3\frac{1}{2}$  years. The studies taught in these courses are the same as in the agricultural course, with the addition of technical subjects bearing on horticulture or forestry, respectively.

The total enrollment at the college in 1894-'95 was 365 students, of which number 301 were from Denmark, 52 from Norway, and the rest from other foreign countries. The different departments had the following attendance: Veterinary 217, agriculture 62, land inspection 22, horticulture 18, forestry 46, and the school in farriery 33 students.

The faculty numbers 28 members, exclusive of assistants in the different laboratories. There are 6 professors, 16 *lektorer* (associate professors), and 6 *docenter* (instructors). The budget of the college is very nearly 200,000 crowns (\$54,000). In the statement of expenditures published the budget of the agricultural experiment station (about \$20,000) is included, and the total expenses are given as follows: For salaries to director, instructional force, inspector, and bookkeeper, \$28,460; for running expenses, \$45,800.

The Danish Parliament in 1892 provided ample means for the reconstruction of old buildings and for the erection of new ones. These were finished in 1895, at a total outlay of about one million crowns (\$268,000).

The Royal Danish Veterinary and Agricultural College in its present condition offers exceptionally good facilities to students, and is an institution of which any State or Nation might well be proud. Its veterinary department remains its strongest part, but the equipment in other lines, both as regards instructional force and working material, laboratories, museums, library, botanical garden, etc., is also complete and fully up to the standard of an institution commensurate with the importance and needs of agriculture and allied industries in Denmark.

#### DAIRY, HORTICULTURAL, AND OTHER SPECIAL SCHOOLS.

In addition to the strictly agricultural educational institutions enumerated in the preceding, some of which offer special courses in branches closely related to agriculture, a number of special schools of this kind are found.

Considering first the dairy schools, there are two higher dairy institutes in these countries, those of Alnarp, Sweden, and Mustiala,

Finland. The courses given at both places are practical as well as theoretical, and last one year. At Ribe, Denmark, a dairy school giving 5-month and 3-month courses in dairying is in operation, and at least two of the elementary agricultural schools, Dalum and Ladelund, give quite complete elementary dairy courses. It is, however, somewhat strange to note that Denmark, whose dairy industry is of such vast importance and has made such remarkable progress during the past 20 years, has no dairy institute or school offering comprehensive advanced instruction in the science and practice of dairying. The course of lectures in dairying given at the Royal Veterinary and Agricultural College by Prof. T. R. Segelcke, the father of modern dairying in Scandinavia, includes 100 to 120 lectures, besides quizzes, the course being given to the agricultural students proper in their senior year. These lectures have been attended by nearly all teachers of dairying in the Scandinavian countries and Finland since the beginning of the seventies, at least by all present leaders in the dairy movement in these countries. Of almost as much importance, and perhaps more so, as far as Denmark is concerned, have been the 2-month to 3-month courses in practical dairying given under Professor Segelcke's direction at a large number of first-class creameries in different parts of Denmark. These courses have been attended by 1,048 students since their inception in 1864.

*The elementary dairy schools* in the other Scandinavian countries are as follows: In Norway, 10—3 for men (Brandbo, Hegre, and Stokke), 7 for women (Sande, Stange, Gaupen, Östensö, Vefsen, Örlandet, and Örsten); length of courses 1½ years. In Sweden, 19—3 dairy schools (Robertsfors, Huså, and Börjksfors), and 16 "dairy stations" (Berga, Bjerka-Säby, Aakerstad, Rjödenäs, Hvilan, Rännum, Kilagården, Ökull, Frugården, Knistad, Torestorp, Rottneros, Trystorp, Stjernerund, Hedensberg, and Näs); length of courses 2 years. In Finland, 17—14 two-year schools (Myrans, Wiurila, Aittamäki, Haga, Pekkala, Järvikylä, Hovila, Simananniemi, Koivikko, Peltosalmi, Mattila, Orisberg, Klaresund, and Ruona), 3 one-year schools (Koivikko, Oulais, and Mnstiala), also 2 herdsmen's schools (Saksala and Löfsta).

*The special horticultural and other schools* are as follows: In Norway, 2 (Aas and Sandnäs); in Sweden, 1 (Alnarp); in Finland, 5 (Helsingfors, Koristo, Kuppis, Kuopio, Haapavesi); in Denmark, 2 (Vilvorde and Beder). The forestry schools are: Norway, 2 (Kongsberg and Stenkjär); Finland, 1 (Evois). And the farriery schools are 1 each in Sweden (Alnarp) and Denmark (Copenhagen) and 3 in Finland (Helsingfors, Aabo, and Wiborg).

#### INSTITUTIONS FOR AGRICULTURAL INVESTIGATION.

The work done in the line of agricultural research in the Scandinavian countries and Finland offers perhaps less of importance to outsiders than the system of agricultural education found there. The

main interest centers around the work of the experiment stations at Copenhagen and Albano (near Stockholm). A few other stations are largely engaged in original investigations, notably the Swedish Moor Culture Association at Flahult and the Seed Improvement Society at Svalöf, Sweden, and important results have been obtained through their efforts. But as regards at least the former of these, similar work on a larger scale and under more varied conditions is being conducted elsewhere. While experiments on agricultural problems are being conducted in all four countries, the attention of the workers, except at the stations at Copenhagen and Albano, is occupied mainly with either instructional or chemical control work instead of investigation. Hence, the continuity and concentration of efforts so essential in investigation is often lacking. This does not prevent these institutions from occasionally publishing, through the perseverance and enthusiasm of their officers, valuable contributions to our fund of scientific agricultural knowledge, as will be apparent from the reports of the institutions reviewed in the Experiment Station Record during the past 5 years. As this work speaks for itself, it will not be necessary to dwell in this article on the results obtained, and attention will be confined to a brief statement of the history of the various stations, their organization, plan of work, officers, means of support, etc.

#### EXPERIMENT STATIONS IN NORWAY.

The control or experiment stations in Norway are as follows:

*The State Chemical Control Station at Christiania* was organized as a separate institution in 1891 and began work February 1, 1892. Previous to that time, since 1863, analyses of agricultural products for private parties had been made by the teacher of agricultural chemistry at Aas or his assistant, for which purpose the Society for Norway's Weal or the Government made a small appropriation, except during a few years (1869-'75) when no money was appropriated from either source. The budget of the station is 12,500 crowns (\$3,378), of which 5,600 crowns (\$1,513) goes to pay the salaries of director, assistant, and janitor. The director reports directly to the Secretary of Agriculture, there being no connection between the station and the agricultural college at Aas. The work of the station is published in the annual report of the secretary and in occasional contributions to the agricultural press. No provisions are made for bringing the results of work done before the public through periodical bulletins or special publications.

During 1895, 897 samples of feeding stuffs, dairy products, fertilizers, water, etc., were sent to the station for analysis. In addition to the control work a goodly number of original investigations have been made and published, reviews of which have been given in the Record.<sup>1</sup>

*Plant Physiological Station at Aas*, established in 1895. The work of the station is largely cooperative and includes the testing of varieties

<sup>1</sup> E. S. R., 5, pp. 537, 1021; 6, pp. 11, 23, 25, 36, 82, 84, 110, 156, 163, 250, 568; 7, pp. 519, 526, 712; 8, pp. 151, 152.

and of systems of rotations at Aas, and at a number of farms in different parts of Norway, thus giving varying conditions as to soil, climate, treatment, etc. The experiments in progress during 1896 were conducted in 12 different places and included the following series of trials: Potatoes (English, German, and Norwegian varieties) 12 series, barley 12 series, oats 16, clover seed 13, lupines 6, infective trials on lupines 21, sugar beets 6, miscellaneous crops 6. The station furnishes the seed and sends an assistant to sow it and to harvest the crops, while the different farmers prepare the soil, take care of the crop during the growing period, and have the crops, minus the small quantities wanted for samples. The assistants have free room and board at the farms while doing the work of the station. The size of the plats are as follows: Oats 28.5 by 42 meters; barley and winter grains 28.5 by 28.5; hay crops—grasses and clovers 20.5 by 49; lupines 32 by 65; potatoes, turnips, etc., 12.5 by 47; and sugar beets 9 by 70 meters.

The station receives 10,000 crowns (\$2,680) annually from the Society for Norway's Weal, but has no State aid. The results of the work done are published in the annual report of the Secretary of Agriculture and in contributions to the agricultural press (E. S. R., 6, p. 543; 8, p. 118). The station staff consists of a director, first assistant, and a number of traveling assistants.

*The chemical department of Aas Agricultural College*, practically without any funds set apart for investigational purposes, has, nevertheless, been able to publish considerable work in this line.<sup>1</sup>

*Milk control stations* are established at Christiania, Trondhjem, and Bergen. Creameries and individual farmers have an opportunity to send in samples of milk for the determination of the fat content, the charges being 10 öre (2.7 cents) per single sample or 5 öre in large numbers. The first two stations were established in 1894, and the third in 1896. During 1895 the stations in Christiania and Trondhjem examined 16,600 and 12,943 samples of milk, respectively, about 95 per cent of the samples coming from creameries. The average percentage of fat in the creamery samples in 1895 was 3.44 for Christiania and 3.41 for Trondhjem. De Laval's butyrometer is used for making the tests. The stations have no officers except a superintendent. The annual State appropriation is 2,500 crowns (\$676) for each station.

#### EXPERIMENT STATIONS IN SWEDEN.

Sweden has 7 chemical stations, largely supported by the Government. Four of these were established in 1876, one in 1881, and two in 1885. They received a State appropriation of 3,000 crowns (\$811) each per year until 1888, when the appropriation for the 4 older stations was increased to 4,000 crowns (\$1,081), and the following year this was extended to all the stations. In addition the various county agricultural societies give annual grants ranging in 1895 from 950 to 4,650

<sup>1</sup> E. S. R., 4, pp. 517, 783; 5, pp. 958, 1017; 6, pp. 199, 250, 475, 927, 1023; 7, p. 979; 8, p. 122.

crowns (\$257 to \$1,257) for the different stations. The income from analysis fees ranged from 1,216.50 to 3,188.60 crowns (\$329 to \$862). In case of 2 stations the director receives all analysis fees and in return pays for chemicals and other materials used. The personnel of the stations generally consists of a director and one or two assistants. The stations publish an annual report giving in more or less detail the results of the work of the year. A summary for each station is also published annually in the report of the Agricultural Department.

The summary of work done by the various stations during 1895 is given in the following table:

*Number of samples analyzed or examined by chemical stations in Sweden during 1895.*

	Jönkö- ping.	Kalmar.	Halm- stad.	Skara.	Örebro.	Vesterås.	Hernö- sand.	Total.
Soils.....	213	51	2	14	21	21	28	350
Soil "amendments".....	117	6	20	19	5	16	3	186
Fertilizers.....	127	233	373	103	91	51	26	1,004
Feeding stuffs.....	72	72	46	27	76	42	67	402
Water.....	64	52	31	144	35	17	109	452
Dairy products.....	12	1,582	6,632	2,209	2,508	16,645	56	29,644
Human food articles.....	117	23	59	7	25	13	34	278
Poisoning cases.....	460	78	2,095	168	812	278	82	3,973
Technical and sundry prod- ucts.....	50	92	27	31	134	28	81	443
Total.....	1,232	2,189	9,285	2,722	3,707	17,111	486	36,732

The sum total of samples examined during the year, as will be seen, is 36,732. It is natural, with this amount of control work to be done, that but little can be accomplished in the line of original investigations of agricultural problems. During the 3 preceding years (1892-'94) 22,461, 26,355, and 35,740 samples, respectively, were examined, showing that the public make use of the stations in an increasing ratio from year to year.

In addition to the preceding stations a number of county agricultural societies have for a number of years past made arrangements with the chemical departments of certain agricultural schools to have chemical analyses made for farmers in their respective counties at a special low rate, and have set apart a certain sum of money annually for this purpose. The number of samples analyzed by such chemical stations during 1895 is shown below:

*Number of samples examined by county chemical stations in Sweden during 1895.*

	Upsala.	Kris- tian- stad.	Alnarp.	Mol- kom.	Gefle.	Umeå.	Grand total.
Soils, etc.....	7	29	21	25	.....	41	.....

Technical and sundry products.....	4	68	21	41	.....	12	.....
Total.....	51	21,658	4,563	225	1,498	208	28,203

Research or control work conducted at Swedish chemical stations has been frequently noted in the Record.<sup>1</sup>

A chemical plant-biological station was established at Luleå in 1895, and began work November 1 of that year, with a director and assistant as its officers. No report has yet been issued from this station.

Variety tests and fertilizer experiments with different crops are made every year at a large number of agricultural schools, and under the auspices of county agricultural societies. So far as known, no regular appropriations are made for this work. The results of the trials are published in the annual report of the Agricultural Department under the summary reports of the various schools.

FIG. 5.—Chemical Department, Experiment Station at Albano, Sweden.

*Experiment Station of the Royal Agricultural Academy at Albano.*—This station (*Experimentalfältet*), founded in 1883, is confined to research work. It has 3 distinct departments—chemical (fig. 5), plant-physiological, and agricultural-horticultural. The officers are a director (chemist), assistant chemist, botanist, and agriculturist. A number of assistants have also at times been temporarily employed. The annual budget of the chemical department is about 12,000 crowns (\$3,243). Special appropriations have been made for buildings, experimental glass house, and garden, etc. The physiological department in 1889-'91 received a special appropriation of 10,000 crowns (\$2,680) for

<sup>1</sup> E. S. R., 4, p. 777; 5, pp. 520, 536, 1025; 6, pp. 109, 241, 373, 577; 7, pp. 247, 520, 669, 701, 717, 826, 845; 8, pp. 151, 153, 154, 161, 168, 173.

conducting investigations on the grain rusts, which Prof. Dr. Jakob Eriksson has made the subject of a special life study. The sum of 7,700 crowns (\$2,080) was at the same time appropriated for the publication of the results obtained.

The work of the experiment station has been, besides the study of the grain rusts, investigations of Swedish forage plants and soils, fertilizer experiments (pot, plat, and field trials) with different crops, cooperative variety tests, dairy experiments, feeding experiments with milch cows, etc. The reports of the work done are published in the Transactions of the Royal Agricultural Academy (*Kongl. Landtbruks-Akademiens Handlingar och Tidskrift*), which appear bimonthly, and also in the periodical press.<sup>1</sup>

*The Swedish Seed Corn Association (Sveriges Utsädesförening)* has an experiment station at Svalöf, Sweden, established in 1886 for the purpose of improving the cereals and other agricultural plants by systematic breeding and selection, so called pedigree culture. The station receives an annual appropriation from the State of 15,000 crowns (\$4,054), also grants from the various county agricultural societies, amounting in 1895 to 16,900 crowns (\$4,568). In addition the State gives 3,000 crowns (\$811) to defray the expenses of distributing the pure-bred seed in trial lots to farmers. In 1895, 41,200 kg. of oats was distributed to 412 farmers. The association has 5 substations in different parts of Sweden, at which improved seed corn is grown on large plats for supplying the material to be distributed during the succeeding year.

The work of the station, under the able direction of Dr. N. Hjalmar Nilsson, has been most successful. A number of new varieties have been propagated, and standard varieties of oats, wheat, barley, peas, and vetches greatly improved. Of the apparatus designed, special mention may be made of the "Svalöf Seed Preparer" (seed coat crusher) for destroying the hard seed coat of leguminous seeds, thus increasing their germinative ability. The new apparatus has a capacity of 1 to 2 bags of clover seed per hour.

The results of the work of the station are published in a quarterly publication, *Svenska Utsädesförenings Tidskrift* (E. S. R., 5, p. 521).

*The Swedish Moor Culture Association* at Jönköping was established in 1886. Sweden has between 12 million and 18 million acres of marsh land still largely uncultivated. The work of the Moor Culture Association, through its investigations and demonstrations at Jönköping (pot and plat experiments) and at Flahult (field experiments), as well as through the publication of its magazine, *Svenska Mosskultur-föreningens Tidskrift*, has largely increased the knowledge of the capabilities of Swedish marshes. The experimental work is planned along similar lines as the experiment station for moor culture at Bremen, Germany.

<sup>1</sup>E. S. R., 4, pp. 768, 963, 965, 971; 5, pp. 808, 1017; 6, pp. 200, 389, 407, 432, 669, 890; 7, pp. 714, 746; 8, pp. 152, 203, 209, 248.

The experimental fields at Flahult, 8 miles south of Jönköping, have a total area of 200 acres, of which 50 acres are under cultivation, 75 acres are unimproved marsh land, 60 acres forest area, and 15 acres buildings, roads, etc.

The Association receives an annual State appropriation of 10,000 crowns (\$2,680), and grants from other sources, county boards, agricultural societies, private parties, etc., aggregating about 25,000 crowns more (\$6,760). Its officers are a director, engineer, and 3 station assistants (E. S. R., 8, p. 297).

#### EXPERIMENT STATIONS IN DENMARK.

In Denmark systematic studies of agricultural problems are pursued at the experiment stations at Copenhagen and at Tystofte, as well as by the Royal Danish Agricultural Society and a number of county agricultural societies.

*Experiment Station at Copenhagen.*—The history of this institution—the Laboratory of the Royal Veterinary and Agricultural College for Agricultural-Economic Experiments—has already been given by the writer in the Record (E. S. R., 6, p. 585), to which article reference is here made. The station publishes occasional bulletins (*Beretninger*), the 36th of which (Investigations of faults in the consistency of butter and of the constitution of the fat globules of milk, by Prof. V. Storch) has recently been noticed (E. S. R., 9, p. 176). The greater share of the work done by the station has been connected with the dairy industry. This station carries on the very important cooperative feeding experiments with milch cows (E. S. R., 6, pp. 585, 657; 8, p. 255) and pigs (E. S. R., 5, p. 428; 7, p. 242), series of which are conducted each winter; also the permanent butter exhibitions (E. S. R., 5, p. 721; 7, p. 626; 8, p. 172), originated by Professor Fjord; and investigations on tuberculosis and its eradication in dairy animals. The tuberculin experiments, conducted on a very extensive scale during the past 4 years, are still in progress, and no official report of the same has yet been published.

The budget of the station for 1894-'95 was as follows:

Salary to assistants in cooperative feeding experiments with milch cows and pigs, and traveling expenses.....	\$9,559
Other expenses connected with these experiments .....	1,566
Chemical department (salaries of 5 assistants, and chemicals and apparatus).....	2,244
Bacteriological department (laboratory experiments) .....	2,443
Animal physiological experiments.....	603
Experiment station, apparatus, labor .....	2,010
Printing.....	1,164
Traveling expenses of director .....	107
Office, executive expenses.....	1,945
Tuberculin experiments.....	2,093
Permanent butter exhibitions.....	6,432
<b>Total.....</b>	<b>30,166</b>

It will be noticed that the salaries and expenses as assistants superintending the cooperative feeding experiments alone amount to nearly \$10,000. The budget for the butter exhibitions during 1894 was \$32,000, of which amount about \$28,000 was for butter; \$25,600 was realized from the sale of the butter, making a loss of \$6,500, which was nearly covered by the special annual appropriation of 24,000 crowns (\$6,432). Beginning April, 1895, this appropriation was increased to 30,000 crowns (\$8,108) per annum.

The chemical department (fig. 6) is in charge of Prof. Dr. V. Storch, and the veterinary-bacteriological department of Prof. Dr. B. L. F. Bang. The regular staff of the station consists of a director, chemist, 5 assistant chemists, veterinarian, assistant veterinarian, animal physiologist, superintendent and 4 assistants connected with cooperative experiments, and bookkeeper, a total of 16 officers. No chemical control

FIG. 6.—Chemical Department, Experiment Station at Copenhagen, Denmark.

work or regular lecture work is done by any of the staff, except the veterinarian, animal physiologist, and one of the assistant chemists, who are also teachers at the Royal Veterinary and Agricultural College.

Abstracts of work done at the station have been given from time to time in the Record.<sup>1</sup>

*Experiment Station at Tystofte.*—The State maintains an experiment station in plant culture located at Tystofte (near Skjelskør, Seeland), with branch stations at Askov, Vester Hassing, and Lyngby. A vast amount of work is done at these stations and at farms cooperating with them in the line of variety tests with cereals, legumes, and roots; experiments as to proper methods of seeding and plowing, hybridiza-

<sup>1</sup> E. S. R., 4, p. 601; 5, p. 721; 6, pp. 585, 657; 7, pp. 242, 253, 254; 8, p. 172.

tion; rotation and fertilizer experiments, etc. (E. S. R., 7, p. 203). The station at Tystofte has an area of about 54 acres, and the branch stations from 19 to 45 acres. The latter are located in different parts of Denmark and represent marked differences as to character of soil, etc.

Investigational work done under the auspices of the State or county agricultural societies or at agricultural schools has largely been limited to analytical work and variety and fertilizer trials, and can only be referred to here.<sup>1</sup>

#### EXPERIMENT STATIONS IN FINLAND.

For a number of years past (since 1881) the Mustiala Agricultural and Dairy Institute has conducted experiments in plant culture, acclimatization and fertilizer tests, feeding experiments with dairy cows, tests of dairy apparatus, tuberculosis investigations, etc., under the direction of the professors at the institute. Only a small sum of money (2,000 marks=\$386) is, however, set apart annually for this work, and what is done is done incidentally, the primary work of the officers being that of instruction. The investigations conducted at the institute are published as reports (*Meddelanden*) of the Agricultural Department, of which 18 have been issued up to date.

An agricultural botanical experiment station was established in Herrenäs in 1889, the special object of which is to make culture experiments with wild grasses and legumes in order to learn their adaptability for permanent pastures. Trials with such plants are also made at a number of private farms, under the direction of the superintendent of the station. The station has an appropriation of 3,500 marks (\$675) per year from the county agricultural society. Only one report has been published, viz, for the years 1889-'93.

Finland has 2 "chemical stations," one at Helsingfors and the other at Aabo. The former was established in 1880 and the latter in 1882. Only control work is done at these stations. The number of samples examined at the Helsingfors station in 1895 was 2,028, and at Aabo in 1894, 905. The budget of the chemical station at Helsingfors is about 15,000 marks (\$2,715). The station staff consists of a director and 2 assistant chemists. Several of its published articles have been noted in the Record.<sup>2</sup>

#### SEED CONTROL STATIONS.

The seed control stations of the Scandinavian countries, of which there are a considerable number, have not been included in the preceding sketch. It is planned to treat these in a separate article later.

<sup>1</sup> E. S. R., 5, p. 813; 6, pp. 455, 936; 7, pp. 206, 224, 491; 8, pp. 153, 161, 173.

<sup>2</sup> E. S. R., 6, pp. 394, 410, 453, 457, 477, 519, 524, 534, 575.

## RECENT WORK IN AGRICULTURAL SCIENCE.

### CHEMISTRY.

**The principal amid of sugar cane**, E. S. SHOREY (*Jour. Amer. Chem. Soc.*, 19 (1897), No. 11, pp. 881-889).—As a result of investigation the author finds that the “principal amid compound present in sugar cane is not optically active, and is not asparagin [as stated by Maxwell<sup>1</sup>], but glyecoll or glyecoin, an amid not heretofore known to occur in plants.” The method of preparing the amid and the physical and chemical characteristics of the crystals are described, together with the ways in which it resembles and is distinguished from asparagin.

Fifteen preparations of glyecoll were made from sugar cane at different stages of growth, including the young shoots of the cane a few weeks old, the green tops of cane 1 year old, and mature cane growing at elevations of from 400 to 1,200 ft. No attempts were made to estimate the quantity, but the author noticed that larger amounts were obtained from young than from mature cane.

“It is fair to conclude that glyecoll is not only the principal amid of sugar cane, but is also a normal constituent of this plant at all periods of its growth. . . . Its occurrence has not been noted in a plant before, and it has been considered a body belonging wholly to animal chemistry. . . .

“The identification of glyecoll in sugar cane and the fact that it has been mistaken for asparagin suggests the probability of its occurrence in other plants, especially the Gramineæ, which forms the major part of the food of herbivorous animals; and it is quite likely that the source of the hippuric acid in the urine of such animals will be found in such occurrence.”

The author considers the matter from the sugar manufacturer's point of view. He has obtained glyecoll in comparatively large quantities from several samples of refuse molasses. He believes that “a body such as glyecoll would exert little effect on the crystallization of sugar one way or the other, especially as it exists in cane in such small amounts, but it is likely that the proteid directly connected with glyecoll will be found to be highly molassigenic.”

**Toxalbumoses which coagulate blood**, M. ELFSTRAND (*Ueber giftige Eiweisse welche Blutkörperchen verkleben*. Upsala: Almqvist & Wiksells Boktryckeri-aktiebolag, 1897, pp. 192).—This is an extended study of the toxalbumoses in croton seed. The poisonous albumen was

<sup>1</sup> Louisiana Stas. Bul. 38, 2. ser. (E. S. R., 7, p. 645).

extracted with water and with a physiological solution of salt from the powdered seed, first removing fat, etc., with alcohol and ether. The greater portion of the book is devoted to a report of experiments on the effect of the croton-seed extract on the blood and blood constituents. The author gives a brief account of previous investigations on croton seed and its poisonous properties, and also on abrin and ricin.

**Report of the chemist, R. DE ROODE** (*West Virginia Sta. Rpt. 1891, pp. 21-41*).—This report is devoted to a brief summary of the work of the year in the chemical department of the station and descriptions of methods for the determination of phosphoric acid in fertilizers, for the analysis of soils, and for the determination of fertilizing ingredients in plants, together with analyses of fertilizing materials, muck, water, soil from experimental plats, and grasses and weeds with reference to food and fertilizing constituents.<sup>1</sup> A method is given for the determination of phosphoric acid and nitrogen in the same weighed sample of fertilizer, which has already been noted.<sup>2</sup> The methods used in the analysis of soils and of the ash of plants are given in detail. The principal advantage claimed for the method of soil analysis is that it calls for larger quantities of soil than are usually prescribed, and thus gives larger precipitates with which to work. In other respects the methods are mainly modifications of well-known processes.

**The determination of nitrogen in organic substances by the Kjeldahl-Wilfarth method, R. DE BÖHTLINGK** (*Arch. Sci. Biol. [St. Petersburg], 5 (1897), Nos. 2-3, pp. 176-196; abs. in Chem. Ztg., 21 (1897), No. 89, Rept., p. 25f*).—The method is recommended for the determination of nitrogen in substances of animal origin. Of solutions use 100 cc., of solids 1 to 3 gm. Add to the substance in a 100 cc. digestion flask 10 to 20 cc. of a solution of 200 gm. of phosphoric anhydrid in 1 liter of pure concentrated sulphuric acid. Add about 0.1 cc. of mercury and heat the flask gently until frothing ceases, then more strongly until the solution is colorless. Allow the solution to cool, fill the flask half full with water, and close it with a rubber stopper while the contents are cooling. Place the solution in a distilling flask with a spoonful of tale and a few drops of alcoholic solution of phenolphthalein diluted with an equal amount of water. Add soda solution (333 gm. per liter of water) until slightly alkaline, and pour in quickly 12 cc. of a solution of potassium sulphid (1 part of the sulphid to 1.5 parts of water). Close the flask immediately with a rubber stopper carrying a condenser, the upright part of which is at least 30 cm. long and of such a diameter that the condensing steam does not obstruct it. Connect the other end of the condenser with a Peligot tube containing 20 to 50 cc. of dilute sulphuric acid, to which a little Congo solution (in water) and sufficient water to close the opening of the tube are added. Distil the ammonia and titrate as usual.

<sup>1</sup> See also West Virginia Sta. Buls. 19 and 22 (E. S. R., 3, pp. 629, 892).

<sup>2</sup> U. S. Dept. Agr., Division of Chemistry Bul. 31 (E. S. R., 3, p. 633).

**The determination of the total volatile fatty acids in butter,** E. WRAMPELMEYER (*Landw. Vers. Stat.*, 49 (1897), No. 3, pp. 215-218).—The author notes two defects in the Wollny method, *i. e.*, the failure to determine all of the volatile fatty acids and the difficulty of completely removing the alcohol used in saponifying. The latter difficulty has been overcome by the use of glycerin-sodium hydrate as proposed by Leffmann and Beam. The author has combined this method of saponification with distillation by means of superheated steam.

The method is as follows: Approximately 5 gm. of filtered fat is saponified in a flask of 700 to 800 cc. capacity with 20 cc. of glycerin-sodium hydrate<sup>1</sup> by heating over the direct flame, and after frothing has ceased 250 cc. of hot distilled water, previously boiled to expel carbonic acid, is added with a drop of indicator (litmus) and 50 cc. of sulphuric acid.<sup>2</sup> The flask is immediately connected with a safety bulb and condenser, and distilled by means of superheated steam generated from distilled and previously boiled water and superheated by passing through a heated copper tube 30 cm. long and 1.4 cm. in diameter. With this apparatus 1½ liters were distilled over in 1½ hours, the distillate being collected in 2 portions of 1 and ½ liters, respectively.

The results of a number of determinations in comparison with other methods are given. The author calls particular attention to the necessity of thoroughly boiling the water previous to use to expel all carbonic acid, and of preventing by mechanical means any of the alkali going over into the filtrate. The results by the new method were considerably higher than those by the Leffmann and Beam method, 5 or 6 cc. more of decinormal alkali per 5 gm. of melted fat being required. This, the author holds, increases the exactness of a determination of the adulteration 15 to 20 per cent, since the numbers for oleomargarin are not higher than those given by the Wollny method.

**The detection of foreign fats in lard and butter,** C. B. COCHRAN (*Jour. Amer. Chem. Soc.*, 19 (1897), No. 10, pp. 796-799).—For detecting beef fat in lard 2 cc. of melted fat and 22 cc. of fusel oil are heated to obtain a perfect solution and then cooled to 16 to 17° C., this temperature being maintained for 2 or 3 hours. A crystalline deposit forms, from which the fusel oil is allowed to drain off, and the residue recrystallized from ether. "By this method I have been able to detect the presence of a smaller amount of beef fat than I could detect when the sample was directly crystallized from ether."

Data for 27 samples of lard and fat of various kinds are tabulated.

For butter or oleomargarin the method is as follows:

"Add 8 cc. of fusel oil to 2 cc. of the filtered fat; warm until a perfect solution is obtained, then cool to 16 or 17° C. A deposit will be formed which, in the few experiments I have made, has been greater in the case of oleomargarin than in

<sup>1</sup>Dissolve 100 gm. NaOH in 100 cc. of water and mix 20 cc. of this with 180 cc. of concentrated glycerin.

<sup>2</sup>Mixture of 20 cc. of concentrated sulphuric acid (sp. gr. 1.84) in 1 liter of water.

butter. When this deposit is crystallized from ether very perfect crystals of large size are obtained. Up to the present time I have only examined 6 samples by this method, 3 of butter and 3 of oleomargarin, and as the crystals obtained in the two cases are in some respects similar, I do not feel able to make a positive statement in regard to the diagnostic value of this test in all cases. However, the difference in the appearance of the crystals, so far as I have yet observed, seems to be sufficiently great to serve as a means of distinguishing butter from oleomargarin."

Report of the chemist, W. B. HARDIN (*South Carolina Sta. Rpt. 1896, pp. 34-38*).—A brief summary of the work of the year in the department of chemistry, including analyses of sweet potatoes (see p. 754), cañaigre, and fertilizers.

## BOTANY.

**Experimental investigations on the assimilation of ammoniacal and nitric nitrogen by the higher plants**, E. LAURENT, E. MARCHAL, and E. CARPIAUX (*Bul. Acad. Roy. Sci. Belg., 3. ser., 32 (1896), pp. 815-865; abst. in Bot. Centbl., 70 (1897), No. 6-7, pp. 232-235*).—The ability of some of the cryptogamous plants to assimilate nitric and ammoniacal nitrogen without the intervention of light has been shown by various authors. In this paper it is shown that the ability to assimilate these substances is not confined to the lower organisms, but is possessed by the higher plants under certain conditions. Leaves and stems, both green and etiolated, of potato, asparagus, barley, beets, elm, maple, and *Aspidistra* were experimented with, 4 lots of each being taken for the different portions of each experiment. The details of the methods of analysis and of the experiments are fully given.

As a result of the experiments it was found that the higher plants require light and particularly the ultra-violet rays for the assimilation of nitrates and ammonia salts and the formation of organic nitrogenous compounds.

Chlorophyll is not necessary for this assimilation, although it greatly facilitates the assimilation of nitric nitrogen. Etiolated plants readily assimilate ammoniacal nitrogen, in fact better than green leaves.

In the assimilation of nitric nitrogen, intermediate products intervene.

It appears that light is not only necessary to the higher plants for the production of energy for the synthesis of the carbohydrates, but also for the production of albuminoid substances.

**On the absorption of organic matter by roots**, J. LAURENT (*Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 22, pp. 887-889*).—The author has made a study of the absorption of glucose and inverted sugar by maize plants grown in water cultures. Before placing the grains of corn to sprout they were thoroughly sterilized, and after sprouting they were suspended in various culture media. The plants grew readily, some of the specimens flowering while growing in the solutions.

Various amounts of glucose and inverted sugar were introduced into the cultures and the plants were found to absorb amounts of these substances about in proportion to their weight. In some cases the absorption was out of proportion, but these were explained by having been larger seed, hence more reserve material at the disposal of the plant.

The saccharine materials absorbed were utilized and a great part given off in the form of carbon dioxide, since the amount absorbed in some cases exceeded the total dry weight of the plant.

**Some considerations upon the functions of stomata,** C. E. BESSEY (*Science, n. ser.*, 7 (1898), No. 158, pp. 13-16).—This paper was read before Section K of the British Association for the Advancement of Science, August, 1897. The author's conclusions are as follows:

"(1) One of the functions of stomata is the admission of carbon dioxide to the chlorophyll-bearing tissues of the plant, for use in the formation of the carbohydrates.

"(2) The loss of water by terrestrial plants was originally hurtful, and is so now in many cases.

"(3) If plants have utilized this constant phenomenon it is for the supply of food matters of secondary importance, as the salts in solution in the water of the soil."

**On the formation of fats in seeds and fruits,** C. GERBER (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 19, pp. 732-735).—The author, from his experiments with olives, castor beans, peach and sweet-almond pits, concludes, with Müntz and Leclerc du Sablon, that the oils are formed in the seed or fruit from the carbohydrates present, particularly from the glucoses. In this he differs with Mesnard, who holds that only the chlorophyll-bearing cells can form oils, which in turn are carried to the reserve cells in the fruit or seed.

**Influence of various substances added to water cultures and of oxygen on the formation of chlorophyll,** W. PALLADIN (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 21, pp. 827-829; also *Rev. Gén. Bot.*, 9 (1897), No. 107, pp. 385-394).—Etiolated plants of *Vicia faba* and *Phaseolus vulgaris*, after being kept in the dark for 48 hours, were brought into the light and various substances added to the water cultures, the effect of such substances on chlorophyll production being noted. The author states that chlorophyll formation was favored when saccharose, raffinose, glucose, fructose, maltose, glycerin, galactose, lactose, and dextrose were added to the culture media. Inulin and tyrosin seemed without any appreciable effect, while chlorophyll production was checked by mannite, dulcitol, asparagin, urea, alcohol, ammonium chlorid, and quinic acid.

Experiments in which the effect of lack of oxygen was noted show that during the formation of chlorophyll it is necessary that more oxygen be given the plants than the amount which they evolve through respiration.

The details of the experiment are fully given in the second publication noted.

**Plant growth with and without argon,** T. SCHLÖSSING, JR. (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 19, pp. 719-722).—The author reports on a series of experiments conducted with oats and *Holcus lanatus* grown in artificial atmosphere in which the argon content was regulated. It was found that argon does not play any important rôle in plant growth.

**Report upon preliminary experiments with the Röntgen rays on plants,** G. F. ATKINSON (*Science, n. ser.*, 7 (1898), No. 158, pp. 7-13, pl. 1).—The author reports 12 series of experiments to test the effect of Röntgen rays on the growth of plants. A large number of phane-

rogams were experimented with, the plants being grown in various conditions of light. In different experiments plants were experimented with from the seedling stage to rather more mature condition. In addition to the flowering plants, experiments were conducted with 3 species of *Mucor*, some chromogenic bacteria, a motile bacillus, and a species of *Oscillatoria*. In the various experiments it was seen that the plant tissues absorbed the Röntgen rays quite freely, but there was no marked influence on the growing parts. There were no visible external injuries, even when the plants were exposed at close range for the greater part of the time during several days.

**Report of the botanist, C. E. BESSEY** (*Nebraska State Bd. Agr. Rpt. 1896, pp. 79-93*).—The author reports on the progress of the botanical survey of the State of Nebraska, and states that now more than 3,200 species of plants are known to be natives of the State. Popular notes are given on pasture, hay, fodder, and silage plants; root and soiling crops; and grains. The culture and use of alfalfa, considered "without question the great forage plant of the Plains," are noted at length.

**Report of the botanist and microscopist for 1891, C. F. MILLSPAUGH** (*West Virginia Sta. Rpt. 1891, pp. 41-47*).—A brief report of the work of the botanical department of the station for the year 1891.

## ZOOLOGY.

Some common birds in their relation to agriculture, F. E. L. BEAL (*U. S. Dept. Agr., Farmers' Bul.* 51, pp. 40, figs. 22).—The food habits and economic importance of cuckoos (*Coccyzus americanus* and *C. erythrophthalmus*) are discussed. The cuckoos are preeminently insectivorous. In 16 stomachs of the black billed cuckoo, 328 caterpillars, 11 beetles, 15 grasshoppers, 635 flies, 3 stink bugs, and 4 spiders were found, as well as a great mass of material too badly broken up to be recognized. In 21 stomachs of the yellow billed cuckoo, collected from May to October, there were found 355 caterpillars, 18 beetles, 23 grasshoppers, 31 sawflies, 14 bugs, 6 flies, and 12 spiders. One stomach contained 12 American tent caterpillars; another, 217 fall webworms.

Like the cuckoos, the various woodpeckers are almost exclusively insectivorous, the redheaded woodpecker destroying large quantities of grasshoppers. What vegetable food they take consists largely of small fruits and berries, such as those of the dogwood, Virginia creeper, etc.

Fifty honeybees, of which 40 were drones, were found in the stomachs of 14 kingbirds. About 90 per cent of the food of the kingbird consists of insects, mostly of injurious species. The habit of preying upon honeybees is much less prevalent than has been supposed. What vegetable food it takes consists of wild fruits of little economic value.

An examination of 80 stomachs of the phæbe demonstrated that over 93 per cent of its animal food consists of insects and spiders, wild fruit constituting the remainder. Grasshoppers in season are eaten to a considerable extent, while wasps and many flies that annoy cattle, and bugs and spiders are eaten regularly.

As shown by an examination of 292 stomachs of the blue jay, 24 per cent of this bird's food consists of animal and 76 of vegetable matter. Some few remains of bird's eggs were found in 3 stomachs, and in 2 stomachs the remains of young birds. In the bird's annual bill of fare the author notes mites, fish, salamanders, snails, crustaceans, beetles, grasshoppers, caterpillars, etc. In 70 stomachs corn was found, in 8 wheat, in 2 oats, and in 158 mast.

The crow, notwithstanding some bad habits, is defended; and as far as possible so also is the rice bird. It is estimated that an annual loss of \$2,000,000 to rice growers is caused by this bird, which, notwithstanding the annual slaughter to which it is subjected in the South, does not seem to decrease in numbers.

Of the red winged blackbird 725 stomachs were examined that showed vegetable food to the extent of 74 per cent. In 238 stomachs of the meadow lark 73 per cent of animal matter was found, which consisted in season largely of crickets and grasshoppers.

The Baltimore oriole is shown by an examination of 113 stomachs to feed largely (34 per cent) upon caterpillars. During its stay within the borders of the United States only about 16 per cent of its food consists of vegetable matter.

Of the crow blackbird 2,258 stomachs were examined, which showed that nearly one-third of its food consists of insects, and that it sometimes eats snails, crayfish, salamanders, small fish, and mice. Only 0.5 per cent of its food consists of the remains of birds and their eggs.

Several sparrows were examined, and while it is acknowledged that they are primarily seed eaters, it is noted that with 3 species—the song sparrow (*Melospiza* sp.), chipping sparrow (*Spizella socialis*), and field sparrow (*Spizella pusilla*)—at least about one-third of their food consists of insects.

The snowbird (*Junco hyemalis*), as shown by an examination of many stomachs, consumes daily about  $\frac{1}{4}$  oz. of weed seeds. Assuming that the birds average 10 to each square mile and that they remain in their winter range 200 days, the snowbirds visiting Iowa consume 875 tons of weed seeds in a single season.

The rose breasted grosbeak is highly commended for the good it has done in destroying the potato beetle. Relative to the cliff swallow, the author claims that it is a mistake to tear down its nest, since it forms a picturesque rather than a disfiguring addition to a building.

The cedar bird, as shown by 152 stomachs, lives almost wholly (87 per cent) upon a vegetable diet which consists mostly of fruit. Only 13 per cent of its food consists of cultivated fruit. This amount was found in only 9 stomachs out of 41 examined during the months of June and July.

Two hundred and thirteen stomachs of the catbird showed that the proportion of vegetable to animal food is as 56 to 44. It is noted that it is only in the Western States, where trees are scarce, that the catbird is seen to any great extent about orchards and gardens.

The brown thrasher, as shown by an examination of 121 stomachs, eats a larger proportion (64 per cent) of animal food.

As shown by an examination of 52 stomachs, the house wren lives almost wholly (98 per cent) upon insects. On the other hand, according to an examination of 330 stomachs, the animal food of the robin amounts to only 42 per cent. Of the 58 per cent of vegetable food, 47 per cent consists of wild fruits.

The food of the bluebird, as shown by an examination of 205 stomachs, consists of 76 per cent of animal and 24 per cent of vegetable matter. In the former there were found 28 per cent of beetles, 22 of grasshoppers, and 11 of caterpillars. Besides, there was a large

number of spiders. During the months of August and September grasshoppers are eaten to the extent of 60 per cent of the birds' food.

**The food of native birds,** W. BAER (*Ornith. Monatsber.*, 3. ser., 5 (1897), No. 8, pp. 125-127).

**The agency of man in the distribution of species,** L. O. HOWARD (*Nature*, 56 (1897), No. 1460, pp. 604, 605).—This is the author's vice-presidential address before the American Association for the Advancement of Science.

**Elements of comparative zoology,** J. S. KINGSLEY (*New York: Henry Holt & Co.*, 1897, pp. 357, figs. 146).—This is an elementary work for high-school and college students, and has the advantage of combining the valuable features of a laboratory guide with an elementary text-book. The figures illustrating representatives of the various orders of the animal kingdom or points in anatomy form an excellent feature, although a new one as laboratory manuals go. Considerable stress is laid upon the value of leading questions in drawing out the student's powers of observation and impelling him to form for himself the conclusions reached by others only after long and patient study. In the same way his comparative faculties are exercised. When he has finished the work the student should have a very fair elementary knowledge of the structural features of most of the orders of the animal kingdom. Under the head of comparative physiology a very brief summary of the chief animal functions is given. An equally brief chapter on the morphology of animals deals with the development of animals, dimorphism, metamorphoses, etc. In a chapter on the animal kingdom it is endeavored briefly to bring out the distinguishing features of plants and animals. An appendix deals with reagents.

## METEOROLOGY.

**Meteorological observations,** J. E. OSTRANDER, J. L. BARTLETT, and A. C. MONAHAN (*Massachusetts Hatch Sta. Met. Buls.* 103-108, pp. 1 each).—The usual summaries of observations and notes on the weather during July-December, 1897. In addition No. 108 gives an annual summary for 1897, the principal data in which are as follows:

*Pressure*<sup>1</sup> (inches).—Maximum, 30.88, March 1; minimum, 29.12, November 9; mean, 30.01. *Air temperature*<sup>2</sup> (degrees F.).—Maximum, 91.5, September 10; minimum, -11, February 1; mean, 46.6; mean sensible (wet bulb), 43.7; annual range, 102.5; maximum daily range, 47.0, October 4; minimum daily range, 3.5, November 19; mean daily range, 20.6. *Humidity*.—Mean dew-point, 39.6; mean force of vapor, 0.402; mean relative humidity, 76.4. *Precipitation*.—Total rainfall or melted snow, 57.05 in.; number of days on which 0.01 in. or more rain or melted snow fell, 127; total snowfall, 52.8 in. *Weather*.—Mean cloudiness observed, 51.4 per cent; total cloudiness recorded by sun thermometer, 2,209 hours, or 50.5 per cent; number of clear days, 108; number of fair days, 109; number of cloudy days, 148. *Wind*.—Prevailing direction, W. or S. 79° W.; total movement, 54,220 miles; maximum daily movement, 400 miles, January 26 and February 3; minimum daily movement, 11 miles, February 1; mean daily movement, 146.8 miles; mean hourly velocity, 6.1 miles; maximum pressure per square foot, 22 lbs., 66 miles per hour on May 10. *Dates of frosts*.—Last, May 8; first, September 22. *Dates of snow*.—Last, April 27; first, November 12.

**Meteorological observations, 1896,** C. S. PHELPS (*Connecticut Storrs Sta. Rpt.* 1896, pp. 288-290).—Notes are given on the weather

<sup>1</sup> Reduced to freezing and sea level. The instruments are 2,735 ft. above sea level.

<sup>2</sup> Temperature in ground shelter 51 ft. below level of other instruments.

during the season, with monthly summaries of observations at Storrs on atmospheric pressure, rainfall, relative humidity, precipitation, and cloudiness, and a record of rainfall at 20 other places in the State during the 6 months ending October 31.

"The total precipitation for the year (40.6 in.), as measured at Storrs, was considerably below the average yearly rainfall for this State. The average for Connecticut from observers having records covering more than 5 years prior to 1896, as given by the New England Meteorological Society, is 48.5 in. The average at Storrs for the past 8 years is 44.2 in., and the average from 15 observers of the New England Meteorological Society in the State having records covering the 5 years prior to 1896 is 44.7 in. The rainfall was unusually large during the months of February and March, while April, May, and June gave an unusually small amount of rainfall. The rainfall throughout the remainder of the growing season was sufficient to keep up a fair growth of nearly all crops. The drought early in the season was sufficiently severe to check the growth of grass and some garden crops, the hay crop being quite light.

"The temperature for January was much below the average, while February and March were about normal. The spring opened quite early, April and May being mild and favorable for farm work. The last damaging frosts in the spring occurred on the 1st and 2d of May. The summer season was notable for several periods of extremely high temperature. Most farm crops except hay made a very fair growth. A light frost occurred September 20, and the first killing frost on September 24, thus giving a growing period of 144 days after the last severe frost in the spring. The average growing season at this station for the past 8 years has been 145 days."

**Report of the meteorologist, G. D. SWEZEY and G. A. LOVELAND** (*Nebraska State Bd. Agr. Rpt. 1896, pp. 139-155, figs. 26*).—This is an account of a study during 1896<sup>1</sup> of the weather and climate of Nebraska in connection with the State Weather Service and in cooperation with the Weather Bureau of the United States Department of Agriculture.

"During the year the number of regular observers has been increased, additional instruments furnished, and an increased issue both of the monthly bulletins and of the weekly crop bulletins distributed to the public and to the press of the State. The number of observers reporting now is 136, the number of weekly crop correspondents during the past season was 215, and the issue of weekly crop bulletins was 1,000."

The temperature and precipitation are summarized for each month, charts showing the isothermal lines, the precipitation, and prevailing winds. A table gives an annual summary of the observations at the different stations on temperature, precipitation, snowfall, and cloudiness.

"The mean annual temperature for the State was 49.4, which is 1.4 above the normal. The lowest temperature was 22 below zero at Lodgepole, on the 27th of November, and the highest was 109, at Norman, on the 26th of July.

"The average total precipitation over the State for the year was 26.19 in., which is 2.86 in. above the normal. The greatest total precipitation was 47.78 in., at Sutton, and the least was 12.60, at Fort Robinson. The greatest local monthly precipitation was 13.77 in., at Rulo, in May. The total average snowfall was 24 in. It was greatest in the northwestern section, where it was 36.4 in., and least in the southern sections, being 16.9 in. in the southwestern and 17 in. in the southeastern. The greatest amount of snow reported was 58 in., at Lodgepole, and the least 0.7 in., at Aurora.

<sup>1</sup> See also Nebraska Sta. Bul. 46 (E. S. R., 8, p. 964).

“The average number of days on which the precipitation amounted to 0.01 of an inch or more was 61, the maximum number being 109, at Omaha.

“The average velocity of the wind over the State for the year was 9 miles an hour, which is 0.5 of a mile an hour above the normal. The maximum velocity was 80 miles an hour at Lincoln on May 12.”

**The weather** (*Ontario Bureau Ind. Rpt. 1896, pp. 38-44*).—Tables give the highest, lowest, mean highest, mean lowest, and mean temperature at the principal stations (8) in Ontario during each month of 1896 and during the period 1882-’96, as well as the annual means; monthly summaries of sunshine observations for the same periods at 5 stations; rainfall and snow during 1895 and 1896 at 71 places; averages for 7 years of temperature, atmospheric pressure, humidity, temperature of dewpoint, cloudiness, direction and velocity of wind, precipitation, etc., at Toronto Observatory; and a monthly and annual summary of observations on temperature, direction and force of wind, and precipitation at Haileybury, Lake Temiscamingue.

**Meteorological observations**, W. B. ALWOOD (*Virginia Sta. Rpt. 1896, pp. 8, 9*).—Tables give monthly summaries (1) of observations on temperature, precipitation, prevailing winds, and cloudiness during the year ending June 30, 1896; and (2) of maximum, minimum, and average temperature and precipitation for the period from June 30, 1893, to June 30, 1896.

**Meteorology in Norway, 1896** (*Aarsber. Offent. Foranst. Landbr. Fremme, 1896, pp. 535-554*).

**Temperature and rainfall**, E. F. LADD (*North Dakota Sta. Rpt. 1896, p. 13*).—A table gives maximum, minimum, and mean temperature and rainfall during each month of 1896 and for comparison the total rainfall of 4 previous years.

**Certain agriculturally important temperature values of northern Southwest Africa**, K. DOVE (*Ztschr. Trop. Landw., 1 (1897), Nos. 11, pp. 271-274; 12, pp. 309-312*).

## WATER—SOILS.

**Experiments on the nitrification of the nitrogenous matter of the soil and of various nitrogenous fertilizers**, P. BONÂME (*Kap. An. Sta. Agron. [Mauritius], 1896, pp. 74-85*).—These experiments consisted in collecting the drainage water from soil to which different fertilizers had been added, and testing it for ammoniacal and nitric nitrogen at stated intervals (every month). Three series of experiments are reported. The first, extending from January 20 to June 26, 1896, was made with galvanized iron pots containing 16 kg. of soil. The second, extending from March 9 to June 13, 1896, was made in the laboratory with glass cylinders holding 900 gm. of soil. The third, extending from June 11, 1896, to February 20, 1897, was made with galvanized iron cylinders holding 3 kg. of soil.

The soil used consisted principally of fine sand (46.3 per cent) and clay (25.5 per cent), and contained 0.115 per cent of phosphoric acid, 0.155 per cent of lime, 0.066 per cent of potash, 13 per cent of oxid of iron and alumina, and 0.35 per cent of nitrogen. Like most of the

soils of Mauritius it was poor in lime, and although it contained a considerable amount of organic nitrogen it was not very productive, because nitrification went on in it very slowly.

The nitrogenous fertilizers tested in different cases were sulphate of ammonia (20.5 per cent of nitrogen), dried blood (13 per cent), oil cake (6.1 per cent), fertilizer (5.4 per cent), and fish guano (6.8 per cent). In duplicate tests of sulphate, blood, and oil cake 5 per cent of calcium carbonate (in form of ground calcareous sea sand) and 1 per cent of lime (50 per cent caustic lime) were applied in addition to the nitrogenous fertilizers. The results are tabulated in full for each experiment.

The results obtained in the last series of experiments, which is probably the most complete, were as follows:

*Amounts of nitric nitrogen in 100 grams of soil at different dates.*

	June 11.	July 12.	Aug. 14.	Sept. 15.	Nov. 26.	Feb. 20.
	Mg.	Mg.	Mg.	Mg.	Mg.	Mg.
Ordinary soil .....	4.2	5.0	5.0	8.3	8.0	8.0
Soil with calcium carbonate .....	6.2	7.3	6.0	10.0	10.0	11.0
Soil with lime .....	17.0	20.0	19.0	24.0	28.0	28.0
Soil with ammonium sulphate .....	22.0	29.0	35.0	44.0	51.0	85.0
Soil with ammonium sulphate and calcium carbonate .....	75.0	133.0	186.0	190.0	187.0	188.0
Soil with dried blood .....	66.0	74.0	85.0	88.0	101.0	101.0
Soil with dried blood and calcium carbonate .....	123.0	151.0	159.0	158.0	174.0	178.0
Soil with oil cake .....	59.0	82.0	95.0	101.0	139.0	155.0
Soil with oil cake and calcium carbonate .....	97.0	139.0	137.0	148.0	155.0	166.0
Soil with fertilizer .....	64.0	90.0	111.0	127.0	140.0	145.0
Soil with fish guano .....	74.0	110.0	113.0	137.0	161.0	164.0

In unlimed soil in all cases sulphate of ammonia nitrified more slowly than the other fertilizing materials, the order of nitrification standing as follows: Fish guano (most rapid), fertilizer, oil cake, blood, and sulphate of ammonia. The addition of lime, especially of caustic lime, increased nitrification to a marked extent in both the fertilized and unfertilized soil, although its action was more energetic on the nitrogen of the fertilizers than on that of the soil. The slowness of nitrification of the sulphate of ammonia appeared to be due to a deficiency of salifiable bases in the soil, since on the addition of lime the sulphate readily nitrified. The other substances used had an advantage over the sulphate of ammonia in that the nitrogen in them was associated with more or less of salifiable bases.

The results indicate in general that in soils well supplied with lime, in a climate such as that of Mauritius, there is not as much difference in the assimilability of the different fertilizers tested as has often been supposed. They also emphasize the importance of lime in rendering the nitrogen of the soil available.

**The mechanics of soil moisture**, L. J. BRIGGS (*U. S. Dept. Agr., Division of Soils Bul. 10, pp. 24, figs. 7*).—This bulletin presents “the application of certain dynamical principles to the problems attending the movement and retention of soil moisture.” A technical discussion

is given of the following topics: Properties of water affecting its retention and movement in the soil—gravitation of water, surface tension, viscosity, and hygroscopic state; properties of films—pressure of a film and surface of no pressure; form of water surface between two soil grains; establishment of equilibrium between two unequal masses of capillary water; salts as affecting the movement of water in soils; temperature as affecting the movement of water in soils; influence of texture and structure of soils on the acquirement and retention of soil moisture; and displacement of capillary water through gravitation.

The water of the soil is considered to be of three kinds: Gravitation water, capillary water, and hygroscopic water. These are defined and the forces and principles involved in their movement and retention are illustrated on the assumption that the soil is made up of spherical particles arranged in different ways.<sup>1</sup> The two great factors in determining the movement and retention of soil water, gravitation and surface tension, are given first attention, a clear distinction being drawn between surface tension and the effective force of a film; and then the modifying influences of viscosity and hygroscopicity are considered.

With the exception of mercury, water possesses a higher surface tension than any other substance which is liquid at ordinary temperatures. The surface tension of water<sup>2</sup> expressed in dynes per centimeter is 75.6 at 0° C. and 72.1 at 25°. The temperature coefficient is thus about —0.14 dynes per degree Centigrade. The surface tension of most aqueous solutions of salt is higher than that of water, and the surface tension increases with the concentration of the solution, as is shown in the following table:

*Surface tension of solutions of salts in water.*

Salt in solution.	Density.	Concentration. <sup>a</sup>	Temperature.	Surface tension.
			°C.	Dynes per cm.
KCl.....	1.170	25	15-16	82.8
KCl.....	1.101	15	15-16	80.1
KCl.....	1.046	7	15-16	78.2
NaCl.....	1.193	25	20	85.8
NaCl.....	1.107	15	20	80.5
NaCl.....	1.036	5	20	77.6
K <sub>2</sub> CO <sub>3</sub> .....	1.357	35	15-16	90.9
K <sub>2</sub> CO <sub>3</sub> .....	1.157	16	15-16	81.8
K <sub>2</sub> CO <sub>3</sub> .....	1.040	5	15-16	77.5
KNO <sub>3</sub> .....	1.126	19	14	78.9
KNO <sub>3</sub> .....	1.047	7	14	77.6
MgSO <sub>4</sub> .....	1.274	24	15-16	83.2
MgSO <sub>4</sub> .....	1.068	6	15-16	77.8

<sup>a</sup> Approximate weight of the dissolved substance in 100 parts by weight of the solution.

“It must be remembered, however, that the surface tension of solutions is very greatly decreased by the addition of very small quantities of certain organic substances produced through the decomposition of vegetable matter. This action is especially marked where there are present substances of an oily nature which do not go into solution, but spread out over the surface in an extremely thin film. Owing to such substances being continually produced by the decay of organic matter, the

<sup>1</sup> Soyka, Forsch. Agr. Phys. [Wollny], 18 (1895), p. 1; Whitney, Agr. Sci., 3 (1889), p. 199.

<sup>2</sup> Smithsonian Physical Tables, 1896, p. 128.

surface tension of the soil moisture is kept very low and could be only slightly influenced by the addition of salts. The application of substances to the soil for the purpose of changing its water content through a change in the surface tension would not, therefore, necessarily be productive of marked results.

"If we take the viscosity<sup>1</sup> of water at 0° C. to be 100, the viscosity at 25° C. is 50, at 30° is 45, and at 50° about 31. This great variation in viscosity with change of temperature is illustrated in the flow of water through soils which King<sup>2</sup> found in his leaching experiments but failed to explain.

"The viscosity of gases in opposition to that of fluids increases with increase of temperature. Air, which is largely used in making so-called 'permeability' determinations of soils, has a viscosity of 0.00017 (1+.00273 t). An increase in temperature of 40° C. would therefore cause the coefficient of viscosity of air to increase one-tenth of its amount. This evidently should always be taken into consideration in determining the physical character of a soil."

Little is definitely known of the nature of the film which constitutes the hygroscopic moisture, and the author proposes to study the subject later.

"The one important factor which determines the acquirement and retention of soil moisture is the curvature of the capillary water surfaces. If equal volumes of 2 soils are placed in contact, and the curvature of the surface is less in the first than in the second, then water will move from the first to the second, increasing the curvature in one and decreasing it in the other until it becomes the same in both soils. If the second soil contains a greater number of capillary spaces than the first, it will contain more water when equilibrium is established. During the adjustment water will have actually moved from a soil containing a low percentage of water to one having a higher percentage. In no case, however, will water leave a capillary space having a water surface of large curvature to go to a space with a surface of less curvature. It is the form of the surface which determines the movement of the water."

**Investigations on the temperature conditions of different kinds of soil**, E. WOLLNY (*Forsch. Agr. Phys.* [Wollny], 20 (1897), No. 1, pp. 133-186).—This is a second contribution to this subject.<sup>3</sup> The previous paper related to the temperature conditions of humus, clay, and quartz-sand soils. The present article is devoted to the temperature conditions in calcareous, magnesian, and ferruginous soils, as determined by observations extending over a number of years. The results are reported in detail and indicate that calcareous and magnesian soils have a decidedly lower heating and cooling capacity than other mineral soils; *i. e.*, they are colder during warm periods and warmer during cold periods. The variations in temperature are also smaller in these soils than in others of mineral origin. As regards the influence of different forms of lime and magnesia, the results indicate that during the warmer half of the year soils containing gypsum are, as a rule, the warmest; those containing calcium carbonate standing next, and those containing magnesium carbonate being the coldest. The variations in temperature are smallest for the gypsum soil and greatest for the calcium carbonate soil. Crystallized calcium carbonate showed a greater

<sup>1</sup> Smithsonian Physical Tables, 1896, p. 136.

<sup>2</sup> U. S. Dept. Agr., Weather Bureau Bul. No. 5, p. 66.

<sup>3</sup> *Forsch. Agr. Phys.* [Wollny], 19 (1896), p. 305 (E. S. R., 8, p. 964).

warming and cooling capacity than precipitated carbonate. The mixing of calcium carbonate with other mineral constituents, clay, sand, etc., had the effect of lowering the soil temperature and reducing the temperature variations. Iron compounds exerted only a slight influence upon the temperature conditions of the soil.

**Investigations on the influence of frosts on the temperature conditions of soils with different salt contents**, R. ULRICH (*Forsch. Agr. Phys.* [Wollny], 20 (1897), No. 1, pp. 218-229).—In these investigations soil (fine kaolin) was mixed in cylinders with 0.05, 0.1, and 0.2 per cent of calcium hydroxid, sodium chlorid, potassium chlorid, calcium chlorid, potassium nitrate, sodium nitrate, potassium sulphate, magnesium sulphate, sodium phosphate ( $\text{NaH}_2\text{PO}_4$ ), potassium phosphate ( $\text{KH}_2\text{PO}_4$ ), potassium carbonate, sodium carbonate, and potassium hydroxid, and subjected to temperatures ranging from  $0^\circ\text{C}$ . to  $-10^\circ\text{C}$ . The results show that the temperature of freezing was lowered by the addition of the salts—the larger the amount of salts present the greater the lowering of the temperature. When the soil water froze the temperature of the soil rose at once to  $0^\circ\text{C}$ ., remained for a time at this point, and then gradually fell under the influence of low temperatures. Certain salts, such as calcium hydroxid, chlorid, and nitrate, retarded this fall of temperature; others, such as potassium hydroxid, phosphate, and carbonate, hastened it. The sulphates exerted no influence in this respect. This difference in behavior of the various salts is partly explained by their effect on the physical character of the soils. The hydroxids, carbonates, as well as the phosphates of the alkalis, make the soil more compact and thus increase its conductivity, while other salts, especially calcium hydroxid, have an opposite effect.

**Soil moisture**, E. F. LADD (*North Dakota Sta. Rpt. 1896*, pp. 9-13).—Monthly summaries (April to October) are given of weekly observations during 1892-96 on soils at depths of from 1 to 3 and 5 to 7 in. Determinations of moisture in soils at two different places in the State where the Campbell method of soil culture was being tested are also reported, and results are tabulated of an experiment undertaken for the purpose of determining the influence of different methods of cultivation on soil moisture during drought. The methods of cultivation were as follows: (1) Ground kept free from growing weeds, but otherwise not disturbed; (2) surface cultivated to a depth of 1 in. every fourth day; (3) surface cultivated to a depth of 3 or 4 in. every fourth day; (4) ground rolled and then the surface stirred to a depth of 1 in. every fourth day; (5) mulched with dry straw manure, and weeds not permitted to grow. The results of this experiment are irregular and inconclusive and the investigation is to be continued.

**Protection and improvement of worn soils**, J. S. NEWMAN (*South Carolina Sta. Bul. 32*, pp. 12, figs. 5).—It is explained that the principal cause of the injury to the cultivated soils of the cotton States is surface washing, which is a result of the system of clean culture and hillside

ditches commonly practiced. Terracing is recommended as "the most, and in fact the only, reliable means of preventing injurious surface washing upon cultivated hillsides," and directions are given for the construction of terraces.

The value of Bermuda grass in preventing washing of the soil and of green manuring in restoring the fertility of washed soil is briefly discussed.

"By a judicious rotation of crops, alternating nitrogen collectors and nitrogen consumers and clean crops with those which supply humus, rapid improvement in both the mechanical condition and the chemical contents of soils may be wrought. Growing renovating crops affords the only practicable means of broadcast manuring on a large scale in a country in which so few stock are kept as in the cotton belt. In our climate we can grow two renovating crops—peas and crimson clover—in one year. If peas are planted in the whole corn crop and follow small grain, renovation will be both certain and rapid."

**The value of plant roots as tillers of the soil,** R. H. ELLIOT (*Jour. Roy. Agr. Soc. England, 3. ser., 8 (1897), pt. III, pp. 467-477*).—In this paper the author discusses the action of roots in disintegrating the soil, their effect on the subsoil, and their direct manurial action as they decay.

The value of roots in maintaining the physical condition of the soil is pointed out. Attention is called to the fact that when land is first plowed up, either from the original turf or an old grass land, the soil is in the same condition as new forest soil, owing to the numerous roots which penetrate it, and that the decline of its fertility is not apparent until this matter has become exhausted, causing the soil to solidify and to become tough and shallow, the physical conditions having been so changed that the land has become a poor medium for plant growth.

In connection with the discussion on the action of roots as subsoiling agents, several examples are given as illustrations. On his own place the author found that chicory penetrated apparently with little difficulty a hardpan about 1 ft. thick and 14 in. below the surface. The roots of burnet and kidney vetch had gone about 20 in., but the alfalfa roots only from 8 to 10 in. It was observed that the strong roots of chicory and burnet had disintegrated the hardpans with their laterals or off shoots. The author considers cropping and drainage the means by which humus is partly consumed and partly washed out of the soil and the protection of a turf composed of deep and strong rooting plants which at once disintegrate the soil and till it to its lowest possible depth the means by which humus can be most profitably restored. By comparing the results obtained from 2 fields after each field had been sown with a mixture of grass, clovers, and deep-rooting plants like chicory and burnet, it is shown that an inferior soil, with no manure other than that of a good turf, and which had never been dressed with barnyard manure, is capable of approximating in yield the best land which has been aided by barnyard manure from time immemorial.

**The fruit soils of Oregon,** G. W. SHAW (*Oregon Sta. Bul. 45, pp. 76-90*).—A discussion of the soils of Oregon from a chemical standpoint. The soils of the eastern, or arid, part of the State differ considerably from those of the humid part and the soils of the southern part of western Oregon differ from those of the Willamette Valley, as shown by the following table:

*Lime, potash, and phosphoric acid in Oregon soils.*

	Willamette Valley.	Southern Oregon.	Eastern Oregon.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Lime.....	0.83	2.22	1.22
Potash.....	.23	.34	.43
Phosphoric acid.....	.21	.13	.14

The author also discusses alkali soils and means of reclaiming them.

**Report of the geologist,** E. H. BARBOUR (*Nebraska State Bd. Agr. Rpt. 1896, pp. 157-172, figs. 11*).—This article reports mechanical analyses of subsoils from 10 different counties of Nebraska and of 3 samples of wind-blown dust, accompanied by a popular discussion of the following topics: Soil survey, soil regions, absorption of water, free water or ground water, capillary water, capillarity assisted and evaporation checked, dust blanket as a protection for soil moisture, hygroscopic water, absorption of storm waters, tendency of cultivation to catch and hold more moisture, desirability of catching and conserving every drop of rain, cracks and fissures in soil, relation of precipitation to imbibition in Nebraska soils, relation of precipitation to the growing season, importance of a moist soil, water needed by growing crops, protection of wind-breaks to plant and soil moisture, annual rainfall of Nebraska not increasing, and relation of irrigation to soils.

The average of the 10 analyses of subsoils is as follows: Moisture in air-dry sample, 3.77 per cent; organic matter, 3.51; gravel, 0.46; coarse sand, 1.04; medium sand, 5.67; fine sand, 15.80; very fine sand, 18.66; silt, 36.34; fine silt, 2.64; clay, 11.89 per cent.

**A reconnoissance in southeastern Washington,** I. C. RUSSELL (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 4, pp. 96, pls. 7, figs. 3*).—This is a description of the geologic structure in and adjacent to the drainage basin of the Yakima River, Washington, and the great plains of the Columbia to the east and south of this area, covering areas in southeastern Washington, northeastern Oregon, and adjacent portions of Oregon. "The region, though not arid, depends for its development upon more complete methods of utilizing the water supply, and this in turn rests upon a thorough knowledge of the underground structure. The latter therefore has been examined and described at some length, as preliminary to a discussion of the employment of the water resources." Special attention is given to the occurrence of artesian waters.

**Artesian well waters**, E. F. LADD (*North Dakota Sta. Rpt. 1896*, pp. 14, 15).—Determinations of the total solids, organic matter, and mineral constituents of 5 samples of artesian well water are reported.

**Chlorin in rain water** (*Agr. Students' Gaz.*, 8 (1897), No. 5, p. 152).—"The rainfall [at Cirencester] for the 6 months ending September 30 was 16.35 in., falling on 87 days; the rain contained as a mean chlorids equivalent to 0.243 grains of sodium chlorid a gallon, that is a total deposit of 12.77 lbs. of common salt per acre. For the 12 months ending at the same date the total rainfall was 33.09 in. on 186 days, and the chlorids equivalent to 30.88 lbs. of common salt per acre."

**The amount of nitrogen conveyed by red clover to different kinds of soil**, N. PASSERINI (*Bol. Scuola Agr. Scandicci*, 3 (1895), pp. 102-111; *abs. in Jour. Chem. Soc. [London]*, 72 (1897), No. 421, II, p. 587).—Box experiments were made with sandy, clayey, and calcareous soils. Only in case of the latter was there a gain of nitrogen, indicating that green manuring is not likely to be successful in soils poor in lime.

**On the improvement of humus soils**, F. DUMONT (*Jour. Soc. Agr. Brabant-Hainaut*, 1897, No. 42).

### FERTILIZERS.

**The preservation of nitrogen as well as the transformation of different forms of nitrogen in barnyard manure**, W. SCHNEIDEWIND (*Jour.-Landw.*, 45 (1897), No. 2, pp. 173-202; *Chem. Ztg.*, 21 (1897), No. 81, p. 841).—It is stated that numerous laboratory experiments tend to show that under certain conditions the amid and ammonium compounds of manure are rapidly lost in the form of ammonia, but that an appreciable loss of nitrogen in the free state occurs only when nitrates are present. The addition of marl reduced the loss of nitrogen from 22.6 to 9.9 per cent, and the use of marl and peat reduced it to 6.1 per cent. It is believed that in the majority of cases the nitrogen is lost principally in the form of ammonia, although in special cases the loss of free nitrogen may exceed that of nitrogen as ammonia.

Investigations on the decomposition of nitrates gave the following results: The addition of water increased the decomposition of nitrates; nitrates decomposed more slowly in old manure than in fresh; increasing the amount of manure applied to a soil increased the amount of nitrates decomposed. In vegetation experiments with soils to which straw and manure poor in nitrogen were applied considerable amounts of nitrates were transformed, part of the nitrogen escaping in the free state and part going into organic combinations.

For the preservation of manure the author thinks attention to the construction, packing, and moisture of the manure heap of more importance than the use of preservatives. Of the latter the most effective seem to be sulphuric acid, sodium bisulphate, calcium carbonate, and caustic lime. The first 2 are effective in preventing all loss of nitrogen when used in sufficient amounts to give an acid reaction (0.4 to 1 per cent in case of sulphuric acid), but they are not recommended, because they may be injurious to the animals and interfere with the rotting of the manure. Sulphuric acid favors the formation of ammonia from the organic nitrogen, but caustic lime has an opposite effect.

The latter checks fermentation and reduces loss of nitrogen by favoring the conversion of ammonia not only into organic combinations but into nitrates, an appreciable amount of which is found in manure treated with lime. Calcium and sodium carbonates acted like caustic lime, but were not so effective.

It is claimed that the principle of preservation should be to conserve the organic and ammoniacal nitrogen as such, or by the use of preservatives to transform these forms of nitrogen into nitrates under conditions unfavorable to the activity of denitrifying bacteria. It is also stated that analysis will not decide the relative merits of different methods of preservation, but that vegetation experiments are necessary for this purpose.

**Commercial fertilizers and chemicals,** R. T. NESBITT and G. F. PAYNE (*Georgia Dept. Agr. Bul. 33, pp. 116*).—This is a report of the fertilizer inspection in Georgia for the year ending June 30, 1897, and includes texts of the various State laws relating to fertilizers, with regulations adopted by the commissioner in accordance with them; notes on valuation; a compilation of analyses of ordinary fertilizing materials; statistics of the consumption of fertilizers in the United States in 1896; suggestions regarding the functions of fertilizers and the profitableness of their use; replies to correspondence relating to various fertilizer questions; notes on the percentage of nitrogen in sea island and upland cotton-seed meal, and tabulated analyses of 1,054 samples of fertilizing materials, including mixed fertilizers, cotton-seed meal, potash salts, phosphates, and other unmixed materials. The amount of fertilizers inspected during the season was 401,979.1 tons, as compared with 335,617.8 tons in the season of 1895-'96. The average composition of the fertilizers analyzed was: Available phosphoric acid 10.87 per cent, ammonia 2.25 per cent, and potash 2.21 per cent.

The following data of the consumption of fertilizers in the United States in 1896 were obtained by correspondence with the various State authorities:

*Consumption of commercial fertilizers in the United States in 1896.*

State and Territory.	Tons.	State and Territory.	Tons.

**Fertilizer inspection,** C. D. WOODS and J. M. BARTLETT (*Maine Sta. Bul. 38, pp. 32*).—This bulletin gives a summary of the provisions of the State fertilizer law, a list of manufacturers complying with the

law in 1897, and tabulated analyses of 30 samples of fertilizers furnished by manufacturers<sup>1</sup>, and 142 samples collected in the open market by a representative of the station.

"The figures which are given as the percentages of valuable ingredients guaranteed by the manufacturers are the minimum percentages of the guarantee. If, for instance, the guarantee is 2 to 3 per cent of nitrogen, it is evident that the dealer can not be held to have agreed to furnish more than 2 per cent, and so this percentage is taken as actual guarantee. The figures under the head of "found" are those showing the actual composition of the samples. . . .

"It is gratifying to note that, as a rule, the fertilizers sold in the State are well up to the guarantee. In a few instances the particular lots of fertilizers sampled are not quite as good as they should be; there is, however, no case which appears to be an attempt to defraud. The comparisons indicate that the manufacturers do not intend to do much more than make good the minimum guarantee and this is all that the purchaser can safely expect."

<sup>1</sup>Analyses of most of the manufacturers' samples were published in Bulletin 33 of the station (E. S. R., 9, p. 436).

## FIELD CROPS.

**Report of the agriculturist, J. H. SHEPPERD** (*North Dakota Sta. Rpt. 1896, pp. 33-41, 48-51*).—The varieties of wheat tested at the station were obtained chiefly from the Northwest, but a number of them came originally from Russia. The sorts which have given the best results in yield and grade for 5 years are Experiment Station Fife, 774 Glyndon, and Red Fife.

Among the 30 varieties of oats, Black Beauty, Tartarian, Race Horse, Giant Yellow, and Archangel have given the best average yield in the variety test for 4 years.

Of 15 varieties of barley grown for 4 years, Manshury, Highland Scotch, Highland Chief, Champion of Vermont, and Chevalier produced the best average yields.

Mercer Flint and Minnesota Flint corn have ripened at the station for 3 years in succession and produced on an average for 2 years  $37\frac{1}{2}$  and  $34\frac{3}{4}$  bu. per acre, respectively. Flint corn is regarded as valuable for feed as dent corn. "The flint varieties usually ripen earlier and seem better adapted to northern climatic conditions than dent varieties."

Dwarf Essex Rape has produced good crops for the past 4 years.

Austrian brome grass (*Bromus inermis*) has been tried at the station and in several parts of the State and is the only new variety of grass which promises to be of particular value. Alsike and mammoth and red clovers yielded in 1896, 1,629, 2,270, and 2,275 lbs. of cured hay per acre, respectively.

The rotation of wheat with spring rye, barley, and oats showed little difference in the following wheat crops from those where wheat followed wheat continuously. Wheat grown after cultivated crops gave a greater percentage increase in yield over wheat grown continuously than wheat after summer fallowing, millet, timothy and clover, flax, field peas, or green manuring with peas and millet. A few plats were manured and planted to corn and the following season to wheat. A decided increase in yield of wheat resulted from the manure. A table showing the plan of the rotation experiments and the results is appended.

**Influence of various amounts of nitrogen on the development of barley, D. N. PRYANISHNIKOV and S. M. KOUZNEZOV** (*Izv. Moscow Selskokhoz. Inst., 3 (1897), II, pp. 53-56*).—The plants were grown in pulverized white sandstone extracted with strong hydrochloric acid. A small amount of chalk was added to counteract any acid. The cylinders used were of glass and contained 3,800 gm. of sand. On the bottom of the cylinder a layer of broken glass was placed, into which was inserted a glass tube for watering. The humidity maintained was 60 per cent by weight of the maximum capacity of the sand for water, which corresponded to 570 gm. of water per pot. The following amounts of fertilizing materials were supplied as recommended by Hellriegel: 0.5168 gm. monopotassium phosphate, 0.2850 gm. muriate of potash, 0.4674 gm. magnesium sulphate, and 1.550 gm. calcium sulphate; and in addition nitrate of soda, which replaced the calcium nitrate usually

employed, was supplied at the following rate: 7.752, 3.876, 1.938 (normal), 0.969, 0.484, 0.242, 0.121, 0.060 gm.

In each cylinder 3 grains of barley were planted June 15. Toward the end of June the plants of the first 3 groups (to which an abundance of nitrogen was supplied) were of a darker green color and more vigorous growth than those of the other groups. The first 3 groups headed out about a week and a half later than in the other groups. This effect of nitrogen was still more marked as regards the formation of the grain. While the plants provided with a moderate or insufficient amount of nitrogen ripened the beginning of September, the plants of the first 3 groups showed a tendency at the end of August to make a new growth without producing any grain. This of course was not exclusively the direct result of the excess of nitrogen, but was partially due to the retardation of maturity caused by this excess. The plants were harvested September 15. The yields were as follows:

*Yields of barley receiving different amounts of nitrogen.*

Experiment.	Amount of sodium nitrate applied.	Crop produced.				Length of plant.	Number of stems with heads.	Weight of 1 grain.
		Grain.	Other above ground parts.	Roots.	Total.			
	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Cm.</i>		<i>Gram.</i>
Group No. 1 .....	7.752	44.30	12.10	56.40	47.6	21	.....	
Group No. 2 .....	3.876	53.00	16.30	69.30	55.2	25	.....	
Group No. 3 .....	1.938	50.80	15.70	66.50	63.5	24	.....	
Group No. 4 .....	.969	8.60	20.25	9.20	38.05	14	0.053	
Group No. 5 .....	.484	5.50	9.80	6.20	21.50	7	.054	
Group No. 6 .....	.242	3.45	6.00	4.10	13.55	6	.048	
Group No. 7 .....	.121	2.60	3.35	2.80	8.75	6	.041	
Group No. 8 .....	.060	1.60	2.85	2.25	6.70	6	.039	

As regards the weight of the plants and the number of stems with heads the plants in experiment No. 2 gave best results.

The percentage by weight of the roots in the total weight of the crops was as follows: No. 1, 21.4 per cent; No. 2, 23.5 per cent; No. 3, 23.7 per cent; No. 4, 24.2 per cent; No. 5, 28.8 per cent; No. 6, 30.3 per cent; No. 7, 32.2 per cent, and No. 8, 33.5 per cent. It appears, therefore, that the relative development of the roots increased as the conditions of growth in general became less favorable.

Analyses of the crop gave the following results:

*Dry matter and nitrogen in the crop produced.*

Where no grain was produced the stalks and leaves contained large amounts of nitrogenous matter.—P. FIREMAN.

**Soil inoculation for leguminous plants,** J. F. DUGGAR (*Alabama College Sta. Bul. 87, pp. 459-488, figs. 12*).—Inoculation experiments with a number of legumes were conducted on various soils in the field and the greenhouse. A disussion of nitrogen-collecting plants, the function of root tubercles, methods of soil inoculation, and the value of winter-growing legumes is given.

October 17, 1896, 4 fortieth-acre plats were sown with seed of hairy vetch. The soil was very poor, but was fertilized at the rate of 400 lbs. per acre of acid phosphate and 120 lbs. per acre of sulphate of potash, no nitrogen being applied. Two of the plats were inoculated. "The seed was dipped in water in which there had been stirred and allowed to settle earth from a lawn once a garden spot where common vetch (*Vicia sativa*) had for several years in succession made a thrifty growth." All plats were cut May 20, 1897. The yields of only 2 plats are given—the uninoculated plat yielded per acre 900 lbs. of green forage, which made 232 lbs. of cured hay, and the inoculated plat produced 9,136 lbs. of green forage per acre, giving 2,540 lbs. of cured hay. The soil of the inoculated plat was left in a better mechanical condition than the soil of the other plat.

Pot experiments were made in the greenhouse with hairy vetch, Canada field peas, crimson clover, alfalfa, white lupine, lespedeza, and cowpeas. The soil for these experiments was taken from an upland rocky cotton field which had been cleared about 20 years, a sandy cotton field cleared about 5 years, a woodland, a lespedeza pasture, and a cowpea field. Special germ fertilizers were used for inoculation in some of the experiments, but the inoculating material for cowpeas consisted of soil taken from around old cowpea roots, and that for lespedeza of soil from the lespedeza pasture. Hairy vetch and crimson clover were inoculated with clover Nitragin, Canada field peas with vetch Nitragin, and white lupines with lupine Nitragin. Alfalfa was inoculated with dust from the seed of bur clover (*Medicago maculata*). The organisms adhering to the perfectly dry bur clover seed had retained their vitality from the time of harvesting in May or June until late in the following October. The cost of inoculating with Nitragin is estimated at \$2.20 per acre. The results of all the experiments are tabulated in an appendix.

Among others, the author makes the following summaries:

"Inoculation with the germ fertilizer or Nitragin greatly increased the yields of all these plants as compared with untreated plants. This increase in the weight of inoculated plants, after thorough drying, was as follows: Hairy vetch, 89 per cent; Canada field peas, 138 per cent; crimson clover (young plants), 146 per cent. Germ fertilizer prepared for vetch was effective on Canada field peas. Inoculation material procured without cash outlay acted like Nitragin and greatly increased the yields of hairy vetch and alfalfa.

"Soil from a field where a given leguminous plant has recently been successfully grown is an effective inoculating material for the same kind of plant when first sown in a soil not already naturally supplied with the required form of germ life.

"The dust adhering to the seed of bur clover was an effective inoculating material for alfalfa; the increase in the first cutting of alfalfa hay following this inoculation was 336 per cent.

"Inoculation for cowpeas and lespedeza was apparently unnecessary in the soils used in these experiments. In or near all of these soils these 2 crops have been growing for years. Hence we may infer that these soils have been previously inoculated by germ-laden dust or by some other natural agency.

"In a soil which for many years had borne no leguminous plants tubercles developed without intentional inoculation on hairy vetch, Canada field peas, crimson clover, and lupines, as well as on cowpeas and lespedeza. This soil was more nearly independent of inoculation than any other soil tested, and yet even on this soil the increase in the weight of inoculated plants over plants not inoculated was 38 per cent with hairy vetch, 58 per cent with Canada field peas, and 79 per cent with crimson clover.

"Many soils are naturally inoculated as regards the most commonly grown leguminous plants, and hence are not benefited by artificial inoculation."

**The color of rye grains, N. WESTERMEIER** (*Abs. in Jahresber. Agr. Chem., 19 (1896), p. 338*).—The grains of 27 heads of Heine improved Zeeländer rye were separated according to their color into the following groups: 5.67 gm. or 6.4 per cent of grayish green grains; 10.068 gm. or 11.3 per cent intermediate between grayish green and light brown grains; 58.68 gm. or 66.4 per cent of light brown grains; and 14.085 gm. or 15.9 per cent of dark brown grains.

The weight per thousand grains is given as follows: The grayish green, 47.25 gm.; intermediate, 45.97 gm.; light brown, 41.07 gm.; dark brown, 38.69 gm. The grayish-green grains were the least in number, but they were heavier than any of the others, while the dark brown kernels were the lightest. The grayish-green color is said not to be caused by the content of the gluten cells, but by the chlorophyll which occurs in the outer cell layers of the seed coat.

These different colored grains were planted in 1894, the plants being allowed to stand about 9 by 9 in. The plants resulting from the grayish-green kernels produced the heaviest grains and the heaviest and largest number of heads, while the grains and heads of the plants from the dark brown seed were smallest in number and least developed. The influence of the color of the seed on the percentage by weight of grains of different color in the resulting crop is shown in the following table:

*Transmission of color of rye grains.*

Color of seed.	In the resulting crop—			
	Grayish green.	Intermediate.	Light brown.	Dark brown.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Grayish green .....	76	8	13	3
Intermediate .....	46	2	49	3
Light brown .....	25	3	66	6
Dark brown .....	17	6	68	9

It is concluded that the chlorophyll content of the seed coat was transmitted to the progeny, and that the dark brown grains, the color of which is believed to have been caused by unfavorable influences during the ripening period, were incapable of transmitting their color.

**The soy bean as a forage crop**, T. A. WILLIAMS (*U. S. Dept. Agr., Farmers' Bul. 58, pp. 3-19, figs. 5*).—This bulletin treats of the general characteristics and origin of the soy bean, the value of the different varieties, the conditions necessary for its growth, the methods of culture and harvesting, and the yield. The composition of the soy bean at different stages of growth, the chemical composition of the various kinds of forage made from the plant, a comparison of the amounts of food constituents produced by an acre of the soy bean and an acre of fodder corn, the percentage of digestibility of the various nutrients, and a comparison of green forage per acre and fertilizer ingredients in the crop and roots of soy beans, cowpeas, and clover are given in tables. Discussions of the chemical composition, digestibility, and value and uses of the soy bean for silage, hay, pasture, and soil renewing are given. The author gives the following summary:

“The soy bean thrives best in soils of medium texture well supplied with lime, potash, and phosphoric acid. It endures drought well, is not easily injured by excess of moisture, and may be grown about as far north as corn.

“The early varieties are best for seed crops, and the medium or late varieties for hay, forage, and silage. Seed may be planted at any time during the spring and early summer, but preferably as soon as the ground becomes well warmed up. Drill one-half to three-fourths of a bushel to the acre; broadcast three-fourths to 1 bushel.

“Little cultivation is needed when growing for forage; when for seed keep weeds down until plants shade the soil. The soy bean may be used for soiling, pasturage, hay, and silage, or the beans may be harvested and fed as grain.

“The forage is very rich in fat and muscle-making materials and should be fed with fodder corn, sorghum, or some other feeding stuffs rich in fat-forming nutrients. The seed can be fed to the best advantage when ground into meal and is almost without equal as a concentrated food.

“Cut for hay when the plants are in late bloom or early fruit; for silage the crop can be cut later, but it is better to cut before the pods begin to ripen; for green forage cutting may begin earlier and continue rather later than for either hay or silage; the crop may be cut for seed after the pods become about half ripe.

“The soy bean is excellent for green manuring and for short rotations with cereal crops. It should be well limed when plowed under as a green manure.”

**Mineral constituents of the sugar cane crop**, P. BONÂME (*Rap. An. Sta. Agron. [Mauritius], 1896, pp. 63-73*).—A very thorough study of the chemical composition, especially the mineral constituents, of sugar cane is reported, the principal results of which are given in the following table:

*Composition of sugar cane at different stages of growth.*

**Field experiments with fertilizers, C. S. PHELPS** (*Connecticut Storrs Sta. Rpt. 1896, pp. 205-215*).—These consist of special nitrogen experiments with corn, legumes, and grasses, and a soil test with fertilizers on oats. Yellow and white flint corn and cowpeas are to be grown under the same conditions for a number of years in succession, and this report is for the second year of the experiment. Each crop occupied 10 plats, 8 of which received 320 lbs. of dissolved bone black and 160 lbs. of muriate of potash per acre. Some of these plats received in addition 25, 50, and 75 lbs. per acre of nitrogen in the form of nitrate of soda or sulphate of ammonia. The unmanured plats were used as check plats. All results are tabulated. Previous work in this line was reported in the Annual Report of the station for 1895 (E. S. R., 8, 398).

The yield of corn was less on the dissolved bone black and muriate of potash plats than on the nitrogen plats. In most cases the yields of the nitrogen plats were less where only 25 lbs. of nitrogen per acre was used than where 50 or 75 lbs. was applied, but the increase in yield was not proportional to the increase in nitrogen. The percentage of protein in the total crop was higher where nitrogen was used and increased with the quantity of nitrogen applied.

A larger yield of cowpeas was obtained from the plats dressed with bone black and muriate of potash than from the check plats. Nitrate of soda increased the yield over all the plats. The effect of nitrogen was not very marked, the largest yield being obtained where the smallest amount of nitrogen was added. "There seems to be very little relationship between the percentages of protein in the crop and the quantity of nitrogen used in the fertilizer."

The soil-test experiment is the seventh in a series, the same kinds of

fertilizers being used on the same plats year after year. The crops were rotated. Where only 1 ingredient was used nitrogen had the greatest influence on the yield, and where 2 ingredients were combined nitrogen and phosphoric acid gave the best results. The plat with all 3 ingredients gave very little increase over the plat receiving nitrogen and phosphoric acid.

**Field experiments with fertilizers,** C. E. THORNE, J. F. HICKMAN, and W. J. GREEN (*Ohio Sta. Bul.* 80, pp. 143-175, fig. 1).—The general plan of this experiment has been outlined in a former bulletin (E. S. R., 8, p. 576). The work comprises fertilizer tests with crops grown continuously on the same land and in 5 and 3 year rotations. This bulletin reports in tabular form the results obtained in 1896 and the average results for the 3 years the experiments have been in progress. The results are discussed and conclusions drawn.

The authors found that on the clay soils phosphoric acid appeared to be the most effective fertilizer constituent for cereals and clover in rotation, but that its full effect was attained only when applied with nitrogen and potash. The quantities of nitrogen and potash in the fertilizers used are considered greater than necessary for the full utilization of the phosphoric acid, and the indications were that nitrogen and potash applied in about equal quantities with phosphoric acid largely in excess makes the most effective fertilizer in proportion to the cost.

"In the continuous culture of cereals nitrogen appears to be the most important constituent of the fertilizer, but as in rotative cropping it is the complete fertilizer containing phosphoric acid and potash as well as nitrogen which produces the maximum effect. . . .

"The cost of the fertilizer has been greater than any increase produced from it in crops grown continuously on the same land in these experiments. When the cereals have been grown in rotation with clover the cost of the fertilizer has been recovered with a margin to spare, provided nitrogen and potash were used in small proportion relatively to phosphoric acid, and when potatoes formed one crop in the 3-year rotation with wheat and clover, it has been comparatively easy to secure a profit on the fertilizer.

"In rotative cropping, ordinary barnyard manure has produced an increase to the value of \$1 to \$1.50 for each ton of manure, this increase being found chiefly in the hay crops, whereas the increase from chemical or slaughterhouse fertilizers is shown chiefly in the grain crops. . . .

"The nitrogen, phosphoric acid, and potash in wheat bran and linseed meal seem to be nearly or quite as effective in producing increase of crop as the same constituents in the ordinary mixed fertilizers of commerce. . . . By proper care of the manure, a large portion—probably the larger portion—of the cost of these valuable feeding stuffs may be recovered in the manure."

**Tests of fertilizers on wheat,** D. O. NOURSE (*Virginia Sta. Bul.* 69, pp. 109-111).—This is in continuation of work reported in Bulletin 47 of the station (E. S. R., 8, p. 221). Suggestions relative to making plat experiments are given, and the results are tabulated.

Nitrogen, phosphoric acid, and potash were applied singly and in combinations of 2 and 3. The standard application consisted of 142.5

lbs. dissolved bone black, 50 lbs. muriate of potash, and 240 lbs. nitrate of soda per acre, "representing the full amount of phosphoric acid and one-half the amount each of potash and nitrogen found in a crop of 25 bu. of wheat per acre."

The yields obtained from the plats to which the phosphoric acid and potash and phosphoric acid and nitrogen had been applied were nearly 3 times as great as those from the unfertilized plats. When applied in combinations of 3 the proportions of the different elements were varied. The standard amount of each element was decreased and increased by one half and applied with the standard amounts of the other 2. The increase and decrease of potash and nitrogen did not seem to have a definite influence on the yield, but in the case of phosphoric acid the yield varied in proportion to the amount supplied. Increasing the standard application of phosphoric acid by one-half did not increase the yield to a sufficient extent to warrant the practice. "On the whole the indications are that fertilizers for this section should contain but a small amount of nitrogen and potash but a large amount of phosphoric acid."

**Report of the agriculturist, D. D. JOHNSON** (*West Virginia Sta. Rpt. 1891, pp. 48-58*).—Presents the needs of the station and gives an outline of experiments in progress.

**Cowpeas, J. G. SMITH** (*U. S. Dept. Agr., Division of Agrostology Circ. 5, pp. 10*).—A reprint of an article from the Yearbook of this Department for 1896 (E. S. R., 9, p. 551).

**Notes on flax culture, H. W. ANDREWS** (*Agr. Students' Gaz., 8 (1897), No. 5, pp. 129-135*).—Notes on the culture of flax for fiber in Ireland with descriptions of the processes of rippling, retting, drying, and scutching.

**The composition of the seed of fodder beets, A. DEVARDA** (*Landw. Vers., Stat., 49 (1897), No. 3, pp. 239, 240*).—The composition with reference to food constituents of 7 varieties and the average composition of the ash.

**The sugar-beet industry (Nebraska State Bd. Agr. Rpt. 1896, pp. 217-299)**.—This is in part a reprint of the papers and addresses presented at the meetings of the Nebraska Beet Sugar Conventions held in 1896. A wide range of subjects was discussed, including the history and condition of the industry in this country and abroad, the world's sugar supply and demand, experiences in sugar-beet culture by practical men, and the growth and probabilities of the industry in Nebraska.

A report by the State sugar inspector on the campaigns of 1891-'95 shows the estimated amount paid out by the factories for labor, beets, and materials used in the process of manufacture, and the total receipts for sugars. A partial list is given of farmers who raised sugar beets, with the amounts they received for the crop, the acreage, and the tonnage per acre.

An address by an architect and designer of beet-sugar factories treats extensively of the erection and operation of beet-sugar factories in Nebraska.

The methods of producing sugar-beet seed are outlined in an address on the production of beet seed in the United States.

**On the effect of humus on the nitrogen content of oats, H. W. WILEY** (*Landw. Vers. Stat., 49 (1897), No. 3, pp. 193-202*).—This article has previously been abstracted from another source (E. S. R., 9, p. 444).

**Methods of curing tobacco, M. WHITNEY** (*U. S. Dept. Agr., Farmers' Bul. 60, pp. 15*).—This bulletin describes the methods of curing Northern Cigar, White Burley, Bright Yellow, Export, and Perique tobacco, and the methods of curing tobacco in Florida. A classification and description of types of tobacco is given. The author makes some suggestions regarding the marketing of tobacco.

**Variations in the quality of wheat grains**, A. SCHISCHKIN (*Deut. Landw. Presse*, 24 (1897), No. 100, p. 909).—The specific gravity, absolute weight, and nitrogen content were determined of 19 samples of 1 variety of wheat grown under systems of rotation without application of fertilizers. The samples represented 19 different seasons. It is shown that the absolute weight of wheat grains varies considerably in different seasons, but that the specific gravity remains comparatively constant. The nitrogen content varied from 2.205 per cent in 1882 to 3.173 per cent in 1891. No connection is believed to exist between the nitrogen content and the absolute weight. The samples from the smaller yields were characterized by a high nitrogen content.

**Experiments on the effect of magnesia on wheat**, N. PASSERINI (*Bol. Scuola Agr.*, 3 (1895), pp. 140–142; *abs. in Jour. Chem. Soc.* [London], 72 (1897), No. 142, II, p. 587).—Applications of magnesium carbonate at rates of 200 to 500 kg. per hectare reduced both yield and quality.

**The prevention of winterkilling of grains** (*Deut. Landw. Presse*, 24 (1897), No. 96, p. 871).—The results of experiments lead to the conclusion that grains are better protected during the winter on lands with a rough surface than on lands which have been smoothed down.

## HORTICULTURE.

**Asparagus culture**, R. B. HANDY (*U. S. Dept. Agr., Farmers' Bul.* 61, pp. 39, figs. 17).—This is a popular bulletin on asparagus culture, including discussions of history, botany and varieties, production of plants from seed, selection of plants, selection and preparation of soils, planting and cultivation, manuring beds, harvesting and marketing, canning and drying, and fungus diseases. The bulletin also contains an article on insect enemies of asparagus by F. H. Chittenden.

In regard to selection of seed, the author recommends that during the spring cutting the plants producing the largest and earliest spears be marked, care being used to have a pollen-bearing plant near the seed-bearing ones to insure pollination. The next spring, one or two of the largest stocks of each of the marked hills should be left, all other stalks being cut for market. These early stalks will then bloom before the later appearing ones, and thus prevent pollination from inferior plants. Of the seed produced by these plants only the largest, plump-est, and best should be used.

In regard to manuring the beds, the author emphasizes the importance of applying fertilizers in the spring and summer when the plant is growing rapidly and storing up reserve material for the next spring's crop of spears, rather than applying it in the autumn or winter when the plant is dormant.

**Department of horticulture and forestry**, C. B. WALDRON (*North Dakota Sta. Rpt.* 1896, p. 19).—A brief report of the work of the year. Experiments with cabbage, cauliflower, and onions gave no results on account of the ravages of cutworms. The experiments with celery lead to the following conclusions:

“(1) The period of transplanting can not safely be delayed after June 1.

“(2) Banking the celery when the soil is excessively dry, especially during warm weather, causes the celery to rot at the heart. To avoid both rust and rot, heavy banking should not begin until cold weather in September.

“(3) The best distance apart for the rows is 4 ft. Under this system alternate rows should be banked and bleached, and then removed when the remaining rows are similarly handled.

“(4) Celery for winter use, planted in boxes, cellars, or pits, should have the roots pruned back to 2 in. in length and the bunches should also receive considerable top pruning, but the outer stalks should not be stripped off.

“(5) White Plume is the best variety so far for general culture.”

**Grafting the apple**, S. C. MASON and I. JONES (*Kansas Sta. Bul.* 65, pp. 18, pls. 7).—In the introduction to the bulletin the authors consider the objections usually urged against grafting. The objection based on the variable character of seedling stocks is considered valid unless the grafts are planted so that roots are thrown out above the point of union of stock and scion, thus placing the trees on their own roots.

Experiments were begun at the station in 1889 to test the merits of various lengths of scions and different portions of the roots for grafting. No. 1 apple roots from French Crab seedlings were used. In the first experiment, uniform 6-in. Ben Davis scions were grafted on different parts of roots. The tops of the seedlings were cut off below the crown and the roots cut into 3 pieces. One hundred grafts were made with the upper part of the roots, 100 with the middle part, and 100 with the lower part, or tips of the roots. About 80 per cent of the grafts made with the upper and middle parts of the roots grew and at 1 and 2 years old there was little difference between the trees grown from them. Of the grafts made with the root tips only 60 per cent grew. The first season the trees of this lot averaged one-third less in height than the other lots and were more slender and weak. The difference was less marked the second year.

The same year that the above experiment was begun 100 Ben Davis scions 2 ft. long were grafted on the upper parts of roots cut below the crown. At 2 years old these trees were about one-half larger and stronger than the trees from 6-in. scions on similar stocks. Many of the tops were so heavy as to necessitate summer pruning.

In 1893 more extensive experiments were begun to test the merits of various lengths of scions and stocks and the merits of grafting above and below the crown. The stocks used were all No. 1 seedlings, regraded to get a more uniform lot. The scions were also as uniform as possible. Winesap, Missouri Pippin, Ben Davis, and Maiden Blush were used in each series of grafts made. Three lengths of scions, 6, 12, and 24 in., were used. With each kind of scion 4 lengths of stocks were used, namely, piece roots  $1\frac{1}{4}$ ,  $2\frac{1}{2}$ , and 5 in. long, and whole roots. For all piece-root grafts the upper parts of roots were used. In all cases except where  $1\frac{1}{4}$  in. stocks were used one-half of the grafts were made 1-in. above the crown and the other half below the crown. Besides the above a number of grafts were made on  $2\frac{1}{2}$ -in. piece roots of small size. In all 9,200 grafts were made. The grafts were stored during the winter under uniform conditions, and in the spring set in

nursery rows. The place of union of stock and scion in all cases was about 3 in. below the surface of the soil.

The percentage of loss was great, owing to the very unfavorable spring and to the grafts having been stored in a cellar which was too warm. The loss with the whole root grafts was least and increased as the length of root diminished. At the end of the first year 81.6 per cent of the whole root grafts were living, 48.5 per cent of the 5 in., 17.2 per cent of the 2½ in., 11 per cent of the small 2½ in., and 6 per cent of the 1¼ in. piece root grafts. At the end of the third season measurements were made of the height of the trees and the diameter of the trunk 1 ft. above the ground. The data obtained are given in tabular form. The greatest growth was made in trees grafted on the longest stocks and the growth declined gradually though slightly with the shorter stocks, being about 11 per cent greater with the whole root than with the 1¼ in. piece root grafts. The trees also showed a tendency to make the best growth from the longest scions, the growth being 11 per cent greater with the 24 in. scions than with the 6 in. ones. There was no constant difference in growth between the trees grafted above the crown and those grafted below it.

In 1894 the above experiment was repeated in part with Winesap, Ben Davis, and Missouri Pippin apples, using 6, 12, and 24 in. scions on whole root, and 5 in. piece root stocks grafted both above and below the crown. Tables are given showing the data obtained from the measurements of the diameter and height of trees grown from the various kinds of grafts. After 2 years' growth there was no constant difference between trees grafted above the crown and those grafted below, either as regards height or diameter. The length of the stocks and scions had a marked influence on the growth, the difference in favor of the long stocks and long scions being practically constant in all cases. The height of 2-year-old trees grafted on whole roots averaged 4.81 ft., and on 5 in. stocks 3.96 ft. The diameter of the former was 0.48 in. and of the latter 0.368 in. The average height of trees from 24 in. scions was 4.79 ft.; from 12 in., 4.37 ft.; and from 6 in. scions, 3.98 ft.; and the diameters were 0.52 in., 0.411 in., and 0.388 in. respectively. From measurements made after 3 years' growth, the authors conclude that the differences due to length of either stock or scion are greater in the first and second years than in the third, the average diameters of 3 trees from 24, 12, and 6 in. scions being 0.788, 0.741, and 0.737 in. respectively.

In 1895 grafts were made with 12 and 6 in. scions on whole roots, 5 in. roots, and 2½ in. roots grafted above and below the crown. In addition a stock grafted above the crown and with roots cut 8 in. long was tested. A table shows the measurements of trees at 2 years old. No constant differences were obtained in favor of either length or style of stock or of grafting either above or below the crown. The trees from 12 in. scions were invariably greater in height and diameter than those from 6 in. scions.

In summing up the experiments the authors say that the difference of growth in favor of the longer scions and stocks is probably not sufficient to compensate for the extra labor and expense made necessary by their use.

Besides the measurements made in the experiments the roots were studied and many photographs made. A number of the photographs are shown in the bulletin and the root characters discussed. From an examination of the roots the authors conclude:

“First, that the main root growth from all lengths of stock is made, in the first year, at or just below the union of the stock and scion; second, that the growth at this point becomes more pronounced in the second and third year’s growth of the tree; third, that growth from the lower portion of the stock is very slight during the first year and becomes of less importance during the second and third; fourth, that this lower growth is greatest on the shorter piece roots and least on the whole root; and fifth, that where the graft is buried deeply a new system of side roots will take the lead at about the usual depth below the surface of the soil, to the more or less complete dwarfing of the lower and earlier root systems.”

The authors believe that the main roots of apple trees are formed naturally near the surface of the soil, and that the use of long tap-rooted stocks therefore is of no advantage except to induce a slightly greater growth the first year or two.

An experiment by F. Wellhouse, president of the Kansas Horticultural Society, showing the effect of different stocks on the growth and longevity of apple trees is given. In 1876 600 grafts each of Winesap, Ben Davis, and Missouri Pippin apples were made on whole root stocks; 600 grafts of each variety were made on 4 in. roots grafted 2 in. above the crown, and 600 on similar roots grafted 4 in. above the crown; and an equal number of grafts of each variety were made on 4 in., 3 in., 2 in., and 1 in. roots, all cut below the crown. In all cases 6 in. scions were used. The grafts were set in the nursery, those grafted above the crown being set so that the union was above the ground. After 2 years’ growth all were taken up and sorted into 2 grades. From the 1,800 grafts made by each method the following percentages of first grade trees were obtained: Whole root stocks, 85.2; 4 in. piece roots, 85.5; 3 in. piece roots, 84.5; 2 in. piece roots, 85.6; 1 in. piece roots, 56.8; 4 in. roots with grafts 4 in. above the crown, 68.6; and 4 in. roots with grafts 2 in. above the crown, 73.6. The roots of the trees grafted above the crown were more irregular than the others. None of the whole root and 4 in. piece root grafts and but few of the 3 in. piece root grafts rooted above the union. Nearly all of the 2 in. and all of the 1 in. piece root grafts rooted above the union. The 2 in. piece root lot was the most satisfactory of all. With all kinds of grafts the original roots of the stocks made little or no growth after being set in the nursery, new roots having been formed in all cases.

About 400 trees of each of the 3 varieties grown from whole root stocks were set in an orchard together with trees from 2 in. piece root stocks. During 19 years no difference in growth, vigor, or fruitfulness

has been observed between them, except that for the first 6 or 8 years the whole root trees threw up from their roots more water sprouts than the piece root trees.

**Prune growing in Oregon,** U. P. HEDRICK (*Oregon Sta. Bul. 45*, pp. 5-75, figs. 18, pls. 4).—This is a popular discussion of prune growing, including climate and soils, planting, cultivating, pruning, thinning fruit, cross-pollination, varieties, stocks, picking fruit, curing and evaporating it, evaporators, diseases of prunes, etc.

About 26,000 acres are devoted to prune growing in the State, mainly in the Willamette and Umpqua River valleys. Rich, loamy river bottom and valley soils are recommended as best for prune growing. Shallow soils are to be avoided. Myrobalan plum is most used as a stock for grafting prunes, though Marianna is considered a better stock by the author, because it does not dwarf the tree, its seedlings are not so variable, its roots do not sucker so much, it unites with all varieties of prunes, and cuttings from it root much easier than from the Myrobalan. Thinning fruit is strongly recommended. Descriptions are given of most varieties of prunes that have been tried in the State and of many others that have succeeded in California.

Descriptive notes on the shot hole fungus (*Cylindrosporium padi*), brown rot (*Monilia fructigena*), black knot (*Plowrightia morbosa*), prune rust (*Puccinia pruni*), curl leaf of the Italian prune, and gummosis are given, together with remedies for each. Studies at the station have led to the belief that "gummosis is the result of a degeneration of the tissues of the tree, brought about by injuries, principally by frost, and secondly sun scald." The author also thinks that overcultivation and lack of drainage may cause the trouble. He recommends wrapping the trees with heavy paper, cloth, or straw to protect them from frost and sunscald, and favors any treatment that will insure thorough maturity of the wood. The author considers the curl leaf of the Italian prune to be closely associated with injury from hot waves to the somewhat delicate epidermal leaf cells of the Italian prune.

**The composition of Oregon prunes,** G. W. SHAW (*Oregon Sta. Bul. 45*, pp. 91-98).—A preliminary investigation of the composition of Oregon prunes is reported. The author briefly discusses the importance of such studies. Tables showing the composition of samples of both fresh and dried prunes of different varieties are given, together with explanatory notes on the analyses.

The average weight of the Petite prunes examined was 24.9 gm., of the Italian prunes, 32.4 gm.; the ratio of pits to fruit in the Petite averaged 1:14, in the Italians 1:19. A comparison of ripe and unripe fruit was made, the ripe fruit being such as fell from the trees after a very gentle shake, and the unripe such a fell only after a very vigorous shake. The comparison showed that from 100 lbs. of fresh ripe fruit there could be obtained 40 lbs. of dried fruit, and from an equal quantity of unripe fruit only 35 lbs. The edible portion of the product of the

ripe fruit contained 25.6 per cent sugar, and that of the unripe fruit 19.18 per cent. The average sugar content of the juice of the Oregon prune was found to be 17.52 per cent, or about 2.5 per cent less than the average for California prunes. On the other hand, the Oregon prunes contained a greater percentage of albuminoids than California prunes, the percentage in the edible portion being 1.32 in the former as against 0.837 in the latter. The composition of the ash of prunes is to be treated in a future publication.

**Vegetable forcing**, H. G. WINKLER (*Columbus, Ohio: The Winkler Book Concern, 1896, pp. 157*).—The book is divided into 3 parts. The first part deals with the management of greenhouse crops, including lettuce, tomatoes, cucumbers, radishes, rhubarb, asparagus, eggplants, celery, peas, and beans. It discusses the methods of culture employed in forcing the various vegetables and gives the varieties of each that are best suited for forcing. The second part of the book has to do with the construction of forcing houses and methods of heating and watering. The third part considers the construction and use of hotbeds and cold frames.

A very considerable part of this work is taken from other books and from experiment station publications. In a few cases no credit is given for the matter borrowed, though the original phraseology has been but slightly modified.

**The kitchen garden: A treatise on the culture of garden vegetables in the open air and in hotbeds**, E. GRIFFON (*Le jardin potager. Traité de la culture des plantes maraichères à l'air libre et sur couche. Tournay: E. Griffon, 1897, pp. 190, figs. 400*).

**The kitchen garden**, L. J. TROUCET (*Le jardin potager. Paris: Larousse, 1897, 2. ed., pp. 181, figs. 190*).

**The manuring of garden plants by means of artificial fertilizers: Practical directions for the use of artificial manures**, R. OTTO (*Die Düngung der Gartengewächse mittelst künstlicher Düngemittel. Praktische Anleitung zur rationellen Verwendung künstlicher Düngemittel. Proskau: A. Kalesse, 1897, pp. VI, 62, figs. 7*).

**Mushrooms and their use**, C. H. PECK (*Cambridge, Mass.: Cambridge Botanical Supply Co., 1897, pp. 80, figs. 32*).—A reprint of a series of articles in *Cult. and Country Gent.*, 1894, May-Sept.

**Composition of haricots, lentils, and peas**, BALLAND (*Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 2, pp. 119-121*).—A table is given showing the maximum and minimum composition of haricots, lentils, and peas, with notes on variations in composition of different varieties. The seeds undergo no change in chemical composition when kept for a long time, but their power of absorbing water diminishes with their age.

**Analyses of sweet potatoes**, W. B. HARDIN (*South Carolina Sta. Rpt. 1896, p. 35*).—Analyses were made of 7 varieties of sweet potatoes grown at the station, and 3 grown elsewhere in the State. The results of the determinations of carbohydrates and water were as follows: Starch, maximum 28 per cent, minimum 23.74 per cent; glucose, maximum 0.78, minimum 0.47; sucrose, maximum 2.8, minimum 1.81; water, maximum 67.55, minimum 63.04.

**Report of the horticulturist**, J. F. C. DU PRE (*South Carolina Sta. Rpt. 1896, pp. 39-44*).—A statement of the work of the year, a list of donations to the department, the amount of rainfall by months, and brief notes on various fruits.

**Russian horticulture**, F. W. TAYLOR (*Nebraska State Hort. Soc. Rpt. 1897, pp. 45-50*).—A brief sketch of Russian pomology from observations made in the summer of 1896. The value of various Russian fruits for introduction into America is considered.

**Revised fruit list** (*Nebraska State Hort. Soc. Rpt. 1897, pp. 230-232*).—Lists of varieties of apples, peaches, plums, cherries, raspberries, and grapes recommended by the Nebraska State Horticultural Society for general planting and for trial in the various fruit districts of the State.

**Book on horticulture: The raising of large and small fruits, the diseases of the same, and the making and care of lawns, R. T. WOODWARD** (*Boston: R. T. Woodward, 1897, pp. 74*).

**Is there permanent prosperity for the Oregon prune industry? H. B. MILLER** (*Oregon Sta. Bul. 45, pp. 1-4*).—A discussion of the law of value as applied to the Oregon prune industry.

**Report upon fruit trees, plants, etc., W. W. BROWN** (*West Virginia Sta. Rpt. 1891, pp. 64-66*).—Brief notes on several varieties of plums, prunes, persimmons, etc., set out for experimental purposes in the spring of 1889.

**Fruits of Ontario, L. WOOLVERTON** (*Ontario Fruit Expt. Stas. Rpt. 1896, pp. 1-40, figs. 67*).—Illustrations, descriptions, and notes on the history and adaptability to Ontario of a number of varieties of apples, pears, peaches, cherries, strawberries, and grapes. The illustrations are all original.

**Records for 1896** (*Ontario Fruit Expt. Stas. Rpt. 1896, pp. 87-115*).—Data obtained from variety tests of several kinds of fruit at a number of substations in Ontario.

**Soils, earths, and composts employed in horticulture, G. TRIFFAUT** (*Sols, terres, et composts utilisés par l'horticulture. Paris: O. Doin, 1896, pp. 308, figs. 3*).—The subject is treated in 2 parts. The first part is a general discussion of soils, their formation and relation to plant growth. It includes chapters on the relation of plants to the soil, general considerations in regard to soils, the physical properties of soils and their modification, and the chemical composition of soils, or the soil as a source of plant food. The second part of the book considers the different types of soils, enumerates the horticultural plants for which each type is suited, indicates the fertilizers to be used with each, discusses the preparation and use of artificial soils and composts employed in horticulture, and gives the chemical composition of a number of fruits, vegetables, and ornamental plants. Some of the principles discussed in the work are illustrated by a description of the culture of azaleas.

**The utilization of fruits in the household and in industrial pursuits, B. L. KÜHN** (*Die rationelle Obstverwertung in Haushalte und gewerblichem Betriebe. Berlin: F. Cynamon, 1897, pp. 209, figs. 60*).—The book treats of the selection of varieties of fruits; the picking, sorting, packing, storing, and shipping of fruits; the manufacturing of dried fruits, jellies, ciders, marmalades, preserves, etc. Many illustrations are given of the implements and apparatus used.

**Fruit evaporation, H. E. BOSCH** (*British Columbia Growers' and Hort. Soc. Rpt. 1895-'97, pp. 99-104*).—Notes on the construction of evaporators and on the evaporation of prunes, pears, and apples.

**A treatise of fruit-tree culture, P. PASSY** (*Traité d'arboriculture fruitière. Paris: J. B. Baillière et fils, 1897, pp. 600, figs. 300*).—The work is published in 3 volumes. The first volume treats in a general way of the establishment of a nursery and fruit garden, planting and arrangement of trees, grafting, pruning, etc. The other volumes have to do with particular fruits, considering in the case of each fruit the special methods of pruning, the principal varieties, and the insect and fungous enemies. The second volume deals with the pear, apple, quince, medlar, etc. The third volume includes the peach, apricot, plum, cherry, almond, grape, gooseberry, currant, fig, walnut, chestnut, hazelnut, etc.

**Peach culture in the open air** (*Garden, 53 (1898), No. 1363, pp. 7, 8; fig. 1*).—The article discusses soil, planting, training, pruning, thinning fruit, varieties, etc.

**Peaches and nectarines under glass, W. TURNER** (*Amer. Gard., 18 (1897), Nos. 154, p. 822; 155, p. 838, fig. 1*).—Notes on culture.

**Japanese persimmons, R. L. WATTS** (*South. Florist and Gard., 5 (1898), No. 1, pp. 18, 19, figs. 3*).

## FORESTRY.

**Influence of spring frosts on the growth of oaks and beeches**, E. GRIFFON (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 15, pp. 548-550).—On May 18 a severe frost was experienced in France, the temperature at Fontainebleau registering  $-8^{\circ}$  C. ( $17.6^{\circ}$  F). Great injury was done to vineyards, forests, etc., and the author examined the succeeding shoots of oaks and beeches to ascertain what effect the frost had had on them. The earlier sprouts were killed, but in June others appeared to take their places. These were abundant on the oaks, but less so on the beeches, and their development was inferior to the normal growth. The supporting and protective tissues were poorly developed, and the secondary woody fibers and sclerenchyma of the cortex were entirely undeveloped. In the leaves the palisade parenchyma was much less differentiated than in the normal leaf.

## SEEDS—WEEDS.

**Experiments on the germination of seeds from different sized fruits and from cells containing different numbers of seeds**, DUKE OF BEDFORD and S. U. PICKERING (*Rpt. Woburn Expt. Fruit Farm, 1897, pp. 160-163*).—The seeds of 100 crab apples averaging 1 oz. each and the same number averaging  $\frac{1}{2}$  oz. were selected, and 60 seeds were taken from the cells containing 2 seeds and 10 from cells containing 1 seed each. These were divided into 6 lots and their germination and viability compared.

Comparing the germination of the seeds from the 1 and 2 seeded cells in each lot of fruit, it was found that the difference was inappreciable, being slightly in favor of the 2-seeded cells.

In the comparison of the percentages of germination of seeds from  $\frac{1}{2}$  oz. and 1 oz. fruits there was found a decidedly higher percentage in the seeds with smaller fruits. Seedlings from the smaller fruits were in nearly every case more robust than from the larger ones.

These experiments are being repeated with other fruits and with 4 sizes of fruits to determine whether it is merely the relative size of the fruits which affects the germinative power of seeds or whether the results given above are due to the size of the fruits being abnormal as compared with the average sized fruits of the tree.

**Investigations of clover and grass seed during 1894**, G. GRO-TENFELT (*Landtbruksstyr Meddel., 1896, No. 18, pp. 71*).—The author reports on the examination of 429 lots of clover and grass seed secured from wholesale and retail dealers and from farmers. The usual data relative to purity, germinative ability, etc., are given.

A report is given on culture experiments made to determine the origin of clover seed, the method by estimation of weed seed not being wholly satisfactory.

Out of 123 samples collected more than two-thirds proved to be either in whole or part of American origin. The author claims that the American clover will not withstand the climate of Finland as well as seed of northern European origin.

The following data compiled from the report gives comparisons of seed of different origin, the seed tested having been secured from wholesale and retail dealers and farmers:

Comparison of European and American red clover seed.

Origin of samples.	Number of samples.	Percentage of germination.			Percentage of viability.			Percentage of weed seed.			Percentage of total impurities.			Weight in gms. of 1,000 seed.

—F. W. WOLL.

**Weeds, J. FLETCHER** (*Canada Cent. Expt. Farm Bul. 28, pp. 44, figs. 16*).—This bulletin gives a general discussion of weed dissemination and methods of eradication and describes the following of the more important weeds: Tower mustard, hare's-ear mustard, tumbling mustard, stink weed (*Thalaspia arrense*), ball mustard, peppergrass, cow cockle, orange hawkweed, viper's bugloss, hound's tongue, Russian thistle, curled dock, and sweet grass (*Hierochloa borealis*). A tabular list of the more prominent Canadian weeds, with their chief characteristics, is given, with methods of propagation and distribution, and suggestions for their eradication.

**The effect of soaking beet seeds, M. E. PHIPPCHENKO** (*Zemledyeli, 1897, pp. 203-205*).—Soaking beet seed has the effect of shortening the period of growth, since soaked seeds germinate on the 4th, 5th, and 6th day after sowing, while dry seed begins to sprout 2 weeks after sowing. The soaking must be done with care. The author recommends the following: Soak the seed for 12 to 14 days at a temperature from 43 to 48° F., using 35 to 40 lbs. of water to 40 lbs. of seed. All the seeds should be equally dampened, but not wet. To secure this they must be frequently stirred.—P. FIREMAN.

**The vitality and the dissemination of seeds, W. W. GLENNY** (*Jour. Roy. Agr. Soc. England, 3. ser., 8 (1897), pt. II, pp. 324-334*).—A popular essay on seed vitality, etc.

**Concerning the individuality of seed of wheat, barley, and peas, W. FELDMANN** (*Beitrag zur Kenntniss der Individualität des Saatkorns bei Weizen, Gerste und Erbsen. Bonn: Friedrich Cohen, 1897, pp. 98, pls. 7*).

**Influence of size of beet seed on the yield and quality of the beets, F. LUBANSKI** (*Zemledyeli, 1897, pp. 154, 155*).—Experiments are reported which indicate that sowing large seed not only gave a larger yield but a higher sugar content.

**The average molecular weight of the soluble matter in germinating seed, L. MAQUENNE** (*Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 16, pp. 576-579*).—Atten-

tion is called to the relation which exists between the freezing point of plant juices and the average molecular weights of the substances contained by them. On account of the varying composition of the plant juices during different periods of germination the freezing point also varies.

**Kansas weeds**, A. S. HITCHCOCK and G. L. CLOTHIER (*Kansas Sta. Bul.* 66, pp. 54, pls. 17).—A catalogue briefly describing 209 species of weeds occurring in Kansas, and giving illustrations of their fruits and seeds.

## DISEASES OF PLANTS.

**New investigations concerning the specialization, propagation, and origin of the black rust**, J. ERIKSSON (*K. Landt. Akad. Handl. Tidskr.*, 35 (1896), pp. 182–198).—The following summary indicates the scope of this paper and the status of knowledge of this subject:

The black rust (*Puccinia graminis*) is found in a number of different specialized forms, characterized not only by their summer and winter spore stage on the grasses, but also by their æcidium stage on the barberry and Mahonia. Three different forms are found on cereals: Rye rust (f. sp. *secalis*), common on rye and barley and also appearing on *Triticum repens*, *T. caninum*, *Bromus secalinus*, and *Elymus arenarius*; oat rust (f. sp. *avenæ*); oat rust, also appearing on *Dactylis glomerata*, *Alopecurus pratensis*, *Avena clatior*, *Milium effusum*, and other grasses; and wheat rust (f. sp. *tritici*), so far found in nature only on wheat. The rye and oat rusts are sharply confined to their respective species of grasses, and there is little danger of their occurring on other kinds of plants. Under certain conditions the wheat rust differs from the other grain rusts in that it may be propagated both in its summer spore and æcidium stages on closely related grains, at least on rye and barley. The rusts of Aira, Poa, and Agrostis are, so far as now known, wholly harmless to the cereals.

Barberry and Mahonia, being bearers of many of the biologically different æcidium forms, of which one corresponds to the rye and barley rust, another to the oat rust, etc., a rusty barberry (or Mahonia) can only infect grains to which its particular rust belongs, if the barberry (or Mahonia) infected with wheat rust be excepted, which can infect not only wheat, but also other cereals, at least rye and barley. By observing the grasses growing in close proximity to a barberry during the preceding fall and winter, one can judge as to its possible harmfulness and determine whether or not it ought to be removed to protect the grain to be grown near it. The propagation of the black rust from rusty grasses to barberry, as well as from barberry to the grasses, may, at least during dry seasons, be disturbed and even prevented, either by a comparatively narrow intervening strip of tree growth (100 meters), or by very small (10 to 25 meters) open spaces. At a distance of 25 meters from a barberry bush the black rust is found to the same extent in all directions. Some differences may be observed according to the luxuriance of the different plants, the most luxurious plants first becoming rusty.

The hypothesis seems warranted, from the facts known, that the first rust spots do not either directly or indirectly owe their origin to a more or less close proximity to barberry, but to a pathological condition of the grass plant itself, a condition which may have originated from an infection of the young plant in the spring by the winter spores of the rust, or from a disease germ carried in the plant from one year to another.—F. W. WOLL.

**Investigations on the specialization of the grain rusts, J. ERIKSON** (*Ztschr. Pflanzenkrank.*, 7 (1897), No. 4, pp. 198-202).—The author continues his observations on the grain rusts. In this paper an account is given of numerous inoculation experiments. In the first series 10 species of grass, representing 6 genera—*Lamarkia*, *Triticum*, *Hordeum*, *Secale*, *Dactylis*, and *Poa*—were inoculated with *Puccinia graminis* from barberry in 1896; and the results of these experiments are reviewed. In every case definite results were secured showing the susceptibility of these species to barberry rust.

In the second series of experiments the inoculation material was taken from the plants previously inoculated from the barberry. It appears that the forms developed on wheat successfully inoculated barley and wheat, but failed on oats and rye. The form grown on *Lamarkia aurea* inoculated that grass and oats. A second form from wheat gave some evidence of successful transfer to barley, but failed on oats, rye, and wheat. The form developed on *Triticum desertorum* failed on wheat and oats, but was successful on the host species, barley, and rye. A third form originated on wheat was very successful in inoculating wheat, but less so when applied to barley, rye, and oats. Spores from *Trisetum distichophyllum* inoculated oats, but failed on wheat and rye. A form from barley infected rye and oats, but produced no rust on wheat or barley. Spores from *Poa casia* produced rust abundantly when transferred to that species of grass.

The information relative to the experiments is tabulated and shows the origin of the inoculation material, inoculated plants, number of infections, and time within which rust pustules developed, etc. The time between the inoculation and appearance of rust pustules varied from 10 to 52 days.

**Eighth annual report of the station, M. HOLLRUNG** (*Jahresber. Vers. Stat. Nematodenvertil. u. Pflanzenschutz, Halle*, 8 (1896); *abs. in Centbl. Bakt. u. Par.*, 2. Abt., 3 (1897), No. 19-20, pp. 535-538).—The report gives an account of the principal fungus and insect enemies of the sugar beet, potato, chicory, garden plants, cereals, legumes, fruits, and forest trees, and the means adopted for combating them.

It is stated that the potato rot due to *Phytophthora infestans* was especially severe on crops grown on heavy soils, while those grown on light sandy soils were almost exempt from injury. Experiments with Bordeaux mixture on the diseased plants are said not to have given entirely satisfactory results. The presence of organisms in the soil

capable of producing scab on potatoes was shown, and soaking the seed tubers in corrosive sublimate solutions for 1½ hours before planting gave good results in preventing scab and also the disease due to *Rhizoctonia solani*.

Notes are given of the occurrence of club root of crucifers, *Penicillium glaucum* on asparagus, mildew of spinach (*Peronospora effusa*), the mildew of cucurbits (*Spherotheca castagnei*), smuts of cereals, and various diseases of fruit trees.

The more destructive insects of these different plants are enumerated, and a brief account is given of the continued studies on the contents of the stomachs of the rook (*Corvus frugilegus*). Definite conclusions relative to the nature of the rook, whether injurious or beneficial to the farmer, are not yet given, and the investigations are to be continued.

**Concerning attacks of black rot, A. PRUNET** (*Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 15, pp. 550-553*).—The author was appointed by the Minister of Agriculture of France to make a study of the black rot of grapes. He has established the periodicity of the disease as shown by the appearance of the well-known spots on the leaves, several attacks occurring during a season. Similar observations are reported by several other investigators.

The severity of the attack is estimated from the abundance of spots on the leaves, and in general the disease seemed to increase rapidly in severity from the first to the third attack, after which it decreased slowly until about the fifth appearance, when it disappeared quite rapidly. The maximum attack on the leaves is about simultaneous with the first invasion of the fruit.

Taking into account the climate, atmospheric conditions, etc., it may be stated that the most disastrous attack on the leaves and axillary organs takes place about flowering time and on the fruit it takes place about the time the grapes are the size of small peas. These two periods usually occur the first in June and the second in July, and are preceded by two invasions of increasing severity. The duration of an invasion for the period of susceptibility to attack varies from 5 to 8 days, dependent on atmospheric conditions, especially the temperature.

In a subsequent publication J. Perraud<sup>1</sup> gives his observations made in 1896 and 1897 in the southeast of France. In general his conclusions relating to the periodicity of development of the black rot agree with the above.

**Observations on canker in plum trees, DUKE OF BEDFORD and S. U. PICKERING** (*Rpt. Woburn Expt. Fruit Farm, 1897, pp. 164-167*).—Notes are given on an apparently hitherto unrecorded disease of plum trees which was due to *Nectria ditissima*. The disease was first noted in the autumn of 1895, when it was found that in a few cases the cortex of a large portion of the stem and of some of the main branches was entirely dead and rotten. The disease had penetrated to a considerable

<sup>1</sup> *Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 19, pp. 728-730.*

distance into the wood, but had not affected the periderm, so there was no external indication of its presence except that the affected portions had not kept up in growth with the rest of the tree. The cortex in the diseased part was brownish yellow and moist and possessed an offensive odor. A somewhat similar appearance was presented by the wood. During the spring of 1896 it was found that many more trees had been attacked, and before the end of the summer 14 out of 93 had been killed. So far as known, cutting out the diseased parts has prevented the spread of the fungus, but it is too early to make any definite statements on this point. It is stated that external injuries do not appear necessary for the entrance of the canker spores. In a large number of cases the disease was present when no visible injury could be found, while instances of bark injury with no infection were quite numerous. This observation tends somewhat to discredit the view that canker is necessarily a wound parasite.

**Some diseases of orchard and garden fruits, A. D. SELBY** (*Ohio Sta. Bul.* 79, pp. 97-141, pls. 9, figs. 9).—Descriptive notes are given of diseases on the gooseberry, raspberry, blackberry, plum, cherry, pear, quince, and apple. Among the diseases of currants and gooseberries the leaf spot and powdery mildew are briefly described, and also the anthracnose of raspberries and blackberries. The red rust of blackberries, leaf spot, a bacterial disease, and crown gall are discussed. The bacterial disease has been determined as due to the same cause as pear blight. The effects are usually visible as brownish dark patches extending around the cane near the surface of the ground. When plantations are seriously affected the canes should be burned. The crown gall of raspberries is said to cause considerable loss. The galls are considered as mostly due to attacks of nematodes. The means for the prevention of this trouble seems to be the destruction of all affected stock, and at the same time care must be taken that other susceptible plants should not be contaminated.

Among the diseases of plum and cherry described are the rot, plum pockets, scab, black knot, shot hole fungus, mildew, and a twig disease accompanied with a gum flow. This disease apparently begins in the region of the buds, which are destroyed and a small dead area formed in the axil of the leaf or at the side of the leaf scar. From this dead area there is usually an exudation of gum, from which fact the disease has been termed gummosis. A similarly diseased condition of the peach is also reported, and both are to be the subject of further study.

The blight, leaf spot, crown gall, and black rot of pears and quinces are described and suggestions given for their prevention. Among the diseases of apples treated are apple scab, sooty fungus, bitter rot, brown spot, sun scald, and crown gall. The causes of these diseases, so far as known, are described and suggestions given for their prevention.

**Anthracnose of the black raspberry, W. PADDOCK** (*New York State Sta. Bul.* 124, pp. 261-274, fig. 1).—This bulletin gives an account

of experiments conducted for 3 years in combating anthracnose of the black raspberry. While the treatment was successful in preventing the disease upon the new canes, the increased yield of fruit did not warrant the expense. The use of healthy plants and short rotation of crops, together with the protection of the new shoots by spraying them in the spring when about 6 in. high with Bordeaux mixture, followed by 2 other applications at intervals of 10 to 14 days, and the removal of all the old canes and badly diseased new ones as soon as the fruiting season is over, is recommended by the author as the best means for combating this disease.

Detailed accounts are given of the experiments conducted at different places, the results of the treatments being tabulated. The canes of different lots were sprayed before the leaf buds opened with copper sulphate solution and with iron sulphate solution, followed by 3 sprayings of Bordeaux mixture. The results seemed to indicate a slight advantage in favor of the use of iron sulphate as a preliminary treatment.

**Field experiments to determine the dependence of bacterial gummosis of sugar beets on conditions of weather and soils,** P. SORAUER (*Bl. Zuckerrübenbau*, 1 (1897), p. 81; *abs. in Centbl. Bakt. u. Par.*, 2. Abt., 3 (1897), No. 19-20, p. 535).—The inoculation experiments of the author are briefly mentioned in which the bacterial origin of the disease known as gummosis was established. Other experiments on a more extended scale are here reported, in which it is stated that sugar beets are especially liable to the disease when overmanured, especially when too much nitrate of potash, lime, and sulphate of ammonia are applied to the soil. The application of large amounts of nonnitrogenous fertilizers seemed to be without effect on the crop, so far as producing disease was concerned. Sufficient water during growth is essential, a long, dry, hot spell of weather being very conducive to the disease.

As preventive measures to be adopted, the author recommends attention to the water supply, by irrigation if necessary, and the application of phosphoric acid to the soil.

**Notes on the diseases of bulbs of *Crocus sativus*,** E. ROZE (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 19, pp. 780-782).—The author mentions the diseases of *Crocus sativus* which are due to *Rhizoctonia violacea* and *Tyroglyphus feculae*, and describes another disease of the bulbs which is said to be due to *Saccharomyces croci*, a new species. The cells of this yeast are ordinarily spherical, colorless, from 2 to 6  $\mu$  in diameter, and spore bearing. In water they are usually elliptical and carry 2 polar spores.

**Experiments in the treatment of fungus diseases of fruit and potatoes,** H. H. LAMSON (*New Hampshire Sta. Bul.* 45, pp. 45-56, figs. 4).—Popular notes are given on the scab of apple and pear, sooty disease of apples, black rot of plums, and blights and scab of potatoes, together with suggestions for prevention of the same.

Experiments on the repression of apple scab, in which Baldwin apple trees were sprayed with a 1: 10 Bordeaux mixture, showed slightly better results when 2 applications of the fungicide were made than when a single spraying was given immediately after blossoming.

Notes are given on a disease of apples and pears characterized by the appearance of dirty or sooty spots on the skin of the fruit. The spots are roundish in outline, varying in size, and often covering nearly or entirely the surface of the fruit. The principal damage caused is the discoloration of the fruit, the fungus being entirely superficial. This disease was most frequently observed on Greenings and Northern Spies, but occasionally was met with on other varieties. Among pears the Beurre de Anjou and Lawrence were most frequently attacked. Spraying with Bordeaux mixture is said to have reduced the disease by at least 75 per cent.

Notes are given on the black knot of plum, as well as suggestions for its prevention by spraying and cutting away diseased portions of the trees.

Experiments were conducted for the prevention of early blight of potatoes in which the different plats were sprayed 2, 3, and 4 times with 1: 10 Bordeaux mixture. The best results were secured when 3 applications were made.

Experiments were also made for the repression of potato scab in which the seed was soaked in corrosive-sublimate solution prior to planting. The different plats were fertilized (1) with commercial fertilizer, (2) with stable manure, (3) with plaster, and (4) with wood ashes. The results obtained show the beneficial effect of treating the seed, but do not fully bear out the statements relative to the effect of fertilizers on scab, the plat receiving stable manure showing the least scab of the series, and that receiving plaster the most. Directions are given for the preparation of Bordeaux mixture and its application.

**Effect of spraying potatoes and of planting at different dates,** DUKE OF BEDFORD and S. U. PICKERING (*Rpt. Woburn Expt. Fruit Farm, 1897, pp. 150-159*).—Experiments have been conducted to test the effect of Bordeaux mixture on potatoes during the seasons of 1895 and 1896. In neither year was the fungus severe in its attack, and the results secured were correspondingly less than they might have been under other conditions. The spraying in all cases increased the vitality of the potato vines and in 1895 increased the total crop 11.6 per cent, the increase averaging 16.7 per cent for the late varieties and 6.5 for the earlier ones. In 1896 the average gain due to spraying was only 2.8 per cent. In this case among the earlier varieties there was an actual loss, which was attributed to the spraying. In all cases there was a greater percentage of large tubers on the sprayed plats.

The experiment on the effect of planting at different times was in the majority of cases decidedly in favor of early planting, the average increase being 27 per cent of the total crop.

**Spraying potatoes on Long Island in the season of 1896, F. C. STEWART** (*New York State Sta. Bul. 123, pp. 234-259, pl. 1*).—The author reports upon experiments conducted at Floral Park and East Williston, Long Island, for the prevention of potato diseases. While all the potatoes were unusually free from disease during the season, yet the sprayed plats showed a considerably increased yield over those not receiving any application of fungicide. The total expense of spraying 5 times is estimated at \$4 per acre. Estimating the potatoes to be worth 25 cts. per bushel, the increasing yield, with the exception of the plat of Victor Rose potatoes, more than paid for the application.

Fungicoid and "Lion Brand" Bordeaux mixture were tested and found to be much inferior to Bordeaux mixture as ordinarily prepared, and are not to be recommended. The insecticidal value of Bordeaux mixture was apparent, but the author thinks that Paris green should be used in connection with the fungicide in spraying potatoes. A comparison was made of different strengths of Bordeaux mixture and the 1:11 formula gave slightly better results than the 1:7 mixture. A comparison was also made in which plants were sprayed 5 times with Bordeaux mixture at the rate of 100 gal. and others at the rate of 50 gal. per acre. The increased yield where the greater amount of fungicide was used more than paid for the additional expense.

**Black rot and grape stocks, E. RATOIN** (*Rev. Sci., 4. ser., 8 (1897), No. 25, pp. 786-788*).—The author cites the resistance of certain varieties to phylloxera and to anthracnose, and mentions the difference in susceptibility of different varieties to black rot. Investigations along the line of resistant varieties is thought promising.

**A general review of the investigations on the grain rusts of Sweden, J. ERIKSSON** (*Bot. Centbl., 72 (1897), Nos. 10, pp. 321-325; 11, pp. 354-362*).—The substance of this article has been given elsewhere (see p. 760).

**On the prevention of grape mildew (Ztschr. Pflanzenkrankh., 7 (1897), No. 5, p. 312)**.—A brief note is given on the beneficial use of copper succrate and sulphur for the prevention of grape mildew.

**Does it pay to spray potatoes? F. H. HALL** (*New York State Sta. Bul. 123, popular ed., pp. 6*).—A popular edition of Bulletin 123 of the station (see above).

**Preventive treatment of raspberry anthracnose, F. H. HALL** (*New York State Sta. Bul. 124, popular ed., pp. 5, fig. 1*).—This is a popular edition of a more technical bulletin of the same number (see p. 762).

## ENTOMOLOGY.

**The California vine hopper, E. W. HILGARD** (*California Sta. Bul. 116, pp. 14, figs. 4*).—Though not so seriously injurious as the Anaheim disease or the phylloxera, the vine hopper is thought of great importance on account of its wide distribution and the absence of any thoroughly good remedy. The lack of a remedy for this insect is accounted for by the peculiarities of its life history. In California in the winter, for instance, the egg state is passed in the ground; nor does the adult insect winter where it may be readily attacked. At that season it leads a somewhat active life, feeding on everything that remains green. The insects begin to increase in the spring and are ready for the vines as

soon as they leaf out. By summer the insects have gradually left other plants and accumulated on the vines. The older and weaker insects die off, reducing the numbers for a while; then about the first of June the first brood reaches maturity, and from this time on the numbers increase again.

The injury to the plant is explained as due to the loss of water from the continual leakage caused by the insect's punctures, which removes the tension necessary to the growth of the plant, and causes premature ripening and loss of the leaves.

The remedies noted are turning sheep into the vineyard, destroying leaves, plowing and rolling, winter spraying, summer spraying, jarring, the use of the hopper dozer, and the net. The first and favorite remedy is not thought worthy of recommendation. There is said to be no evidence in favor of its employment. The second remedy is considered equally worthless. The third may destroy a few, but the results will not justify the expense. Winter spraying is worthless; summer spraying, although effectual, scarcely pays when the difficulty and cost are taken into consideration. In such spraying a strong wash, like kerosene emulsion, must be used. Jarring is one of the best methods, and several pieces of apparatus for use in this method are figured. In California the favorite apparatus resembles a large scoop with a net in front and with the hind edge bent to receive the handle. The use of a large insect net is also recommended.

The plan of trying to exterminate the insects has been found by repeated trials to be impracticable, and, since it is only the excessive numbers of the insects that are injurious, the author proposes the plan of merely trying to reduce the numbers below the danger line—about 50 per cent in the worst years.

“According to the best estimate we could make by actual trial in the field of the effect of the use of the net in the spring, it appeared that a much larger percentage than that could be destroyed—nearer 90 per cent, and this, to, while working at a rate of about 5 acres a day. About half of a gang of men, green hands at the business, part white and part Chinese, did almost as well as one skilled with the net. At the rate of wages they were getting, the cost per acre would be between 15 and 20 cts. This makes it a wonderfully cheap process. If it cost twice as much, and had to be done a dozen times a year, it would not begin to cost as much as the loss to a crop in a bad year. It seems to have been proven by actual test that a good percentage of the hoppers can be taken and killed by the use of the net and at a cost per acre that is nominal. There yet remains to be seen whether the vineyardist can develop a judgment that is to be depended on as to when the insects are approaching the danger point, and to set the nets going. According to this new theory of treatment, it would appear that we have the true solution of the problem and that the net or the palm-leaf fan are the means giving the greatest promise.”

**Insects of the prune**, A. B. CORDLEY (*Oregon Sta. Bul. 45, pp. 99-127, pls. 3, figs. 4*).—This bulletin was compiled to enable Oregon fruit raisers to recognize the various insects that attack the prune. Although prunes have been grown in Oregon for some years the insects that affect the trees elsewhere are only beginning to be introduced. It

is thought that native insects may soon learn to attack them. The insects mentioned are classified according to the part of the tree affected. In some cases very complete accounts of the life history and habits of the insects are given, together with the principal, more or less well-known, remedial measures.

The peach tree borer (*Sanninoidea exitiosa*) promises to be one of the worst insect enemies of the prune in the State. It was introduced into the State nearly 20 years ago and is spreading rapidly. The Pacific peach tree borer (*S. opaleseens*) is thought to be present in the State and to take the place of *S. exitiosa* in southern Oregon. The flat headed apple tree borer (*Chrysobothris femorata*), the cicada (*Platypedia putnami*), the branch and twig borer (*Polycaon confertus*), the San José scale (*Aspidiotus perniciosus*), the bud moth (*Tmetocera ocellana*), the clover mite (*Bryobia pratensis*), the red spider (*Tetranychus* sp.), the prune leaf weevil (*Tricolepis inornata*), plant lice (*Aphis prunifolia* and *Phorodon humuli*), the peach twig moth (*Anarsia lineatella*), and the box elder plant bug (*Leptocoris trivittatus*), are the other prune pests mentioned.

The bud moth appears to be recorded for the first time in Oregon, where it has been found at Portland affecting the cherry. Although it has not been found affecting prunes, it is included in the list on account of its well-known fruit habits in the East. The remedy suggested for it is under-spraying the leaves with Paris green between June 1 and 10.

The peach twig moth has been found affecting both peach trees and prunes. The insect was studied somewhat in detail. It was noted that notwithstanding a rather extensive attack of the insect in June no evidence was found during the summer, fall, and early winter months of an attack on the prune by a second brood. From this and the fact that in early fall strawberry plants were very badly attacked by an apparently identical larvæ the author infers that the July brood of moths deposits its eggs almost entirely upon the strawberry. A specimen of the moths raised from larvæ taken from the strawberry was identified by C. H. Fernald as *Anarsia lineatella*. The appearance of the moths from larvæ affecting the prune and those from larvæ affecting the strawberry is almost the same, save that the former are somewhat larger and darker in color. The habits of the moths and the coloration of the larvæ are, however, very different and therefore the author thinks that 2 distinct insects have been confused under the name *Anarsia lineatella* or that dimorphism occurs. Which is the true *A. lineatella* is a question left undetermined, but it is suggested that one of the species may possibly be *A. pruinella*, which has been discarded as a synonym of *A. lineatella*. The moths reared from strawberry crowns crawl down the vines into the crevices in the soil and when disturbed run or flutter about with wings half spread, while moths from larvæ affecting the prune take an elevated position in the breeding cage with the fore part of the body somewhat raised and the labial palpi held rigidly upward. When disturbed they dart rapidly away and alight again in the same peculiar attitude.

Winter spraying with strong kerosene emulsion, or a lime-salt-sulphur wash is recommended for destroying the half-grown larvæ in their winter quarters. The best remedy is thought to be spraying with Paris green when the leaf buds are unfolding.

**Report upon insect pests found in the Northern District,** W. W. FROGGATT (*Agr. Gaz. New South Wales*, 8 (1897), No. 10, pp. 716-720, pl. 1).—Among the large number of injurious insects mentioned, the most important from the amount of damage done is the maize moth (*Heliothis armigera*), which was found in several fields attacking corn to the extent of 75 per cent; the silver spotted plusia (*Plusia verticillata*); the orange pest (*Monolepta rosa*); the harlequin fruit bug (*Dindymus varicolor*); the larvæ of a moth, probably *Conogethes punctiferalis*; the castor oil plant pest (*Achaea melicerata*); and the fruit fly (*Tephritis tyroni*).

The destruction of magpies, larks, and fly catchers is deprecated since they all feed upon the maize moth.

The castor oil tree moth (*Achaea melicerata*) is described and figured. The larvæ strip the plants of foliage, and when ready to pupate make their way into the stalks. The moth ranges widely, being found in India, Ceylon, Celebes, and Moreton Bay, Queensland. Balfour, in his work on the "Agricultural Pests of India," says: "The larva is called *Thondala hoola* by the Canarese. They feed upon the castor oil plants, the leaves and flowers of which they eat; on 2 or 3 acres of land, in one night, they will leave nothing but bare branches. The plants seldom survive their attack, and at best yield only one-fourth of the produce. The cultivators drive them from the plants by smoking, but this is impossible of application when seeds are sown on an extensive area, in which case the husbandman gives up all hopes of the crop."

The caterpillar is about 1½ in. long, of a general reddish chestnut with a darker chestnut stripe on either side. The head is mottled with creamy white spots. The legs are reddish yellow, claws black, the claspers blotched with white. The caterpillars exhibit considerable variation in color.

The acacia pod moth (*Arotrophora ombrodelta*) is also described. The larvæ were found infesting the pods of the ornamental acacia (*Acacia farnesiana*). The larvæ were plentiful in the pods in May, and were found pupating in June. The moths emerge in August. The only way to get rid of the pests is to collect all pods as soon as ripe and treat them with bisulphid of carbon.

**How flowers attract insects: Experimental researches,** F. PLATEAU (*Bul. Acad. Roy. Sci. Belg.*, 3. ser., 33 (1897), pp. 17-42).—The author briefly reviews some of the literature that has appeared on this subject and gives the results of experiments of his own along the same line. In general he concludes that insects manifest neither preference nor antipathy for the colors of the flowers of any particular species or related species. They go without hesitation to nectarless flowers, habit-

ually neglected, in which honey has been placed. They cease their visits when the nectiferous portions of flowers are removed and begin them again when honey is placed in flowers so treated. The experiments were performed by counting the number of visits per hour to certain flowers. For example, 4 individuals of *Megachile cricetorum* showed no preference for the various colors of *Centaurea cyanus*; the first went from white to blue, from that to purple, and thence to white flowers. The second from white to blue, thence to blue. The third from rose to purple and thence to white. The fourth from blue to rose, to blue, and thence to blue. Similar observations were made in connection with rose, scarlet, yellow, orange, and white varieties of *Dahlia variabilis*; likewise in connection with *Scabiosa atropurpurea*, *Linum grandiflorum*, and *L. usitatissimum*, and the results compared with those obtained by Darwin with *Dictamnus fraxinella*, *Delphinium consolida*, *Primula veris*, and by Bonnier with *Centaurea cyanus*, *Althea rosea*, *Digitalis purpurea*, *Epilobium spicatum*, and *Brassica oleracea*. In regard to color Plateau's results are entirely confirmatory of those obtained by these authors.

**The activity of worker bees in the collection of honey**, L. DEFOUR (*L'Apiculteur*, 40 (1897), No. 12, pp. 300-312, figs. 6).—The daily and hourly variations in weight of a hive of bees were studied during the season of 1896 with a view to obtaining light on the relations between the going and coming of the workers, the number of bees, the honey collected, etc. The first weight taken in the morning was chosen as the zero point from which to measure the variations. The hourly weights were used in plotting curves. As a result of the weighing, it was found that at Fontainebleau there are 2 periods of good honey flow and 2 of bad. The first of the latter begins the season and is followed by the first of the former extending from the latter part of May into June and July. Most of the summer is occupied by the second of the poor periods of honey flow and is followed by the second period of good honey flow, beginning in August and extending into September. The first of the 2 periods of good honey flow is due mostly to acacia and the second to heather bloom. It was also found that during periods of comparatively poor honey flow the daily curve obtained shows peculiar and characteristic features. The bees during the first hour or hour and a half in the morning leave the hive in small numbers and then at the end of this time begin to depart in very large numbers, so that the hive sinks rapidly in weight. Finally a point of minimum weight is reached, after which the weight of the hive begins to increase, slowly at first and then more rapidly. It then begins to decrease again until it reaches in the afternoon a second minimum weight, after which it progressively increases in weight until the evening. By comparison with the experiments by Bonnier on the flow of nectar, Defour comes to the conclusion that this rise in the weight of the hive during the middle of the day corresponds to the period of small flow of nectar, which occurs during the hottest part of the day.

When nectar is abundant, however, there is no such midday rise in the weight of the hive, which shows that the bees go and come continuously throughout the whole day. Further, the rate of departure of the bees from the hive when nectar is abundant is practically the same until the minimum weight is reached.

**Bee keeping**, F. BENTON (*U. S. Dept. Agr., Farmers' Bul. 59, pp. 32, figs. 19*).—A brief popular treatise on this subject. The results to be expected from bee keeping are candidly set forth. The annual production per colony is given as from 30 to 35 lbs. of extracted, or 20 lbs. of comb honey, worth, according to current prices, from \$2.50 to \$3.00. From this one-third is deducted as a reasonable allowance for labor, etc.

As food plants there are listed the following: Filbert, rape, orchard fruit blossoms, locust, tulip trees, clovers, mustard, asparagus, esparciet, serradella, chestnut, linden, cotton, chicory, pot herbs, alfalfa, parsnips, peppermint, bokhara or sweet clover, cucumber, squash, pumpkin, melon, eucalypti, the carob tree, sachaline, and buckwheat.

Relative to wintering, it is stated that outdoor wintering where conditions are within easy control, even though the preparation for such wintering is greater, is preferable for all except experienced bee keepers who may prefer indoor wintering. The great desideratum in wintering is to retain the warmth of the bees while at the same time preventing the accumulation of moisture in the hive. For securing this a peculiar device of the author's is described, in which the essential features are a single wall of cloth or similar porous material and a space between this and the outer or thick wall filled with waste wool, hay, hemp, or similar material, and the standing of the frames on end to secure deeper comb.

Foul brood and bee enemies are described in the latter part of the bulletin. The best remedy for the former is thought to be the removal of the affected bees, the destruction of the combs, and after first fasting the bees for 48 hours, feeding them for 48 hours with medicated honey or sirup (one part carbolic acid to 600 or 700 parts of honey or sugar sirup) at the rate of  $\frac{1}{2}$  lb. daily.

**How to cure foul brood among bees**, W. McEVoy (*Amer. Bee Jour., 37 (1897), No. 21, pp. 370, 371*).—According to the author's method—which has the advantage of saving the bees and of building up weak colonies, while at the same time curing them—the combs in the honey season are removed from diseased hives in the evening. The bees are all carefully shaken back and then given foundation starters. On this the bees are allowed to work for 4 days. Then in the evening the combs that have been made from the starters are removed and replaced by foundation. This process, according to the author, will completely cure the colony.

Foul broody combs from several hives may be stored in an empty two-story hive, which should be closed up and shaded from the sun. By this time most of the brood will have hatched and the entrance may then be opened and the combs removed and the bees given foundation

starters in a single hive. They should then be allowed to build combs for 4 days. At the end of this time in the evening the comb may be replaced by foundation and the bees given a queen cell ready to hatch.

The honey in the diseased combs may be extracted, but all uncapped cells should first be cut out and heated to the boiling point, after which it may be fed back to the bees. All of the foul combs and those built in the 4 days should be buried or placed beyond the possibility of access to the bees.

At the close of the honey season the queens in all the weakest colonies should be caged for about 10 days, so no brood can be started. The brood from strong colonies is then removed and tiered up on the weak ones with the caged queens. The process of giving starters and foundation to the strong colonies is then gone through with and the bees fed sugar sirup in the evening during the first 4 days.

At the end of 10 days the combs from the weak colonies may be removed and the bees shaken into a single hive and given foundation. The queens may now be released and the bees fed sugar sirup for 4 days. The combs at the end of this time are to be removed and replaced by foundation.

**Report of the State Board of Agriculture on the extermination of the gypsy moth** (*Massachusetts State Bd. Agr. Rpt. 1896, pp. 349-396, pls. 1*).—It is reported that the moth has been exterminated from most of the outlying towns and its spread prevented, but 2 new colonies of long standing having been found in Brookline. According to the opinion of the entomologist, it will take 15 years to exterminate the pest and will require an annual appropriation of \$200,000 for 5 years, of \$100,000 for the succeeding 5 years, and of \$15,000 for the balance of the time.

The field director reports that a line can now be drawn excluding two-thirds of the area formerly infested. This outer area is nearly or not entirely free from the moth.

During the year 10,718,836 fruit, shade, and forest trees were inspected, 57,723 of which were found infested, 567,025 of which were burlapped, 4,327 sprayed, 90,820 trimmed, and 929 scraped. A large number of buildings and fences were also inspected and found infested to a greater or less degree. In all, there were destroyed 1,808,105 caterpillars, 441,899 pupæ, 44,291 moths, and 884,928 unhatched egg clusters. There were found, besides these, 31,501 hatched clusters.

As a forest pest the insect substantiates its former reputation for destructiveness. Oak trees stripped for 2 seasons in succession are now found dead or dying. In a few instances death seems to follow a total defoliation in one year and only a partial one the next. Death seems to begin at the top, the limbs presenting a sunburned appearance. The attacks of bark borers finally hastens the work of destruction.

The methods employed in combating the pest are much the same as in former years. To the list of bird enemies reported in 1895 there are added the red winged blackbird (*Agelaius phoeniceus*) and several

undetermined species of sparrows. Most of the birds named feed on the caterpillars.

**Report of the State entomologist for 1895, J. A. LINTNER** (*11th Rpt. of the Injurious and Other Insects of the State of New York for the year 1895; reprinted from the 49th Rpt. New York State Museum, pp. 87-325, figs. 25, pls. 16*).—This contains very complete accounts of some 29 insects. In an appendix there is given a list of insects affecting the apple, which includes 6 species of Hymenoptera, 157 of Lepidoptera, 6 of Diptera, 118 of Coleoptera, 50 of Hemiptera and Homoptera, 3 of Thysanoptera, 2 of Arachnida, etc. The rest of the appendix is devoted to a bibliography of the author's publications.

Worthy of special note among the insects is the plan of destroying the little red ant (*Monomorium pharaonis*) by exploding the vapor of carbon bisulphid introduced into their holes; so also is the statement that the larvæ of the tussock moth (*Notolophus (Orgyia) leucostygma*) has been found at Albany girdling the young twigs of the American elm ever since the phenomena was first recorded in 1883. During the latter part of August, 1896, twigs of unusual length with perfectly fresh leaves were collected beneath a large American elm. Each had been broken at the base of the girdle, which was near the node of the year's growth. The tips varied in length from 10 to 18 in. and had fallen on account of girdling, not in the early part of the season, but in late summer. In discussing the genista caterpillar (*Mecyna reversalis*) this insect is noted as occurring on Long Island, feeding on a species of genista and cytisus in the greenhouse and also out of doors.

The new insects described are the melon vine midge (*Diplosis cucumeris*), the hairy melon vine midge (*Diplosis setigera*), and an unknown species of *Anthomyia* as a raspberry cane maggot. It is stated that the attack of this insect may be distinguished from that of the raspberry cane girdler by the absence of the 2 rings of punctures between which the egg of the *Obera bimaculatata* is placed, although the tips of the affected twigs bend over in the same manner. A further difference is found in the time of the attack. That of the fly occurs in May and that of the beetle in the latter part of June.

A new mite, the carnation mite (*Tyroglyphus lateromorphous*), is also described. It was found in the greenhouse in Berlin, Massachusetts, where carnations were observed dying gradually at the base. The stems generally began to decay just below the ground. Sometimes the whole plant and at others individual branches would show signs of weakness. An examination of the plant disclosed in most of them, near the surface of the ground, large burrows, in which were found numerous mites of the species named, together with eel worms and several other mites of a larger size, different species and genus (*Gamasus*). At least 5 different forms of the mite, representing as many developmental stages, were found. The hypopus was found within the body of the female.

**The fall army worm: Southern grass worm, A. L. QUAINANCE** (*Florida Sta. Bul. 40, pp. 507-512, figs. 3*).—From several localities in

Florida reports were received that the fall army worm (*Laphygma frugiperda*) has been unusually abundant and destructive during the late spring and early summer of this year. In consequence of these reports the author published this bulletin, which deals briefly with the food plants of the insect, its manner of feeding, noting that in Florida it seems to be partial to crabgrass and to crowfoot. Besides, there is given a description of the insect in its different stages, of its habits, natural enemies, and treatment. Among the insect's enemies the wasp (*Polistes bellicosus*?) is noted.

Spraying with Paris green at the rate of 1 lb. to 125 to 150 gal. water is advised. If the larvæ are not observed until very much damage is done and the grass is rapidly disappearing, the best remedy then would be to plow them under as deeply as possible. In other cases a large roller might be used to crush the larvæ. Trees may be banded with cotton to prevent the worms from ascending the trunks when their grass food has given out.

**Tendons and muscles of Hymenoptera**, C. JANET (*Études sur les fourmis, les guêpes, et les abeilles*, 12 note. Limoges: (1895), pp. 25, figs. 11; abs. in *Jour. Roy. Micros. Soc.* [London], 1897, No. 5, pp. 376, 377).—The author describes the muscles and tendons and articular membranes of bees, ants, and wasps. Each muscle fiber he considers as multi-nucleated, the sarcolemma representing the cell membrane.

**The palps of butterflies**, E. REUTER (*Acta Soc. Fenn.*, 22 (1896), pls. 6; *Ann. Mag. Nat. Hist.*, 6. ser., 20 (1897), pp. 114, 115; abs. in *Jour. Roy. Micros. Soc.* [London], 1897, No. 5, p. 376).—The author studied the palps of 670 species of butterflies belonging to 302 genera. Special attention was given to external form, the hairy or scaly covering, and the basal spot—which is striated, pitted, and studded with numerous conical hairy scales. The results obtained are used in an endeavor to erect a genealogical tree. The Hesperiidæ are given distinct subordinal rank under the term Gypocera.

**The natural history of ants**, C. JANET (*Paris: Société Zoologique de France*, 1896, pp. 36; abs. in *Jour. Roy. Micros. Soc.* [London], 1897, No. 5, pp. 374, 375).—This is a lecture on the habits and life history of ants. As a type *Myrmica rubra* is chosen, and successive stages in the life of the individual described. As a change in the animal's habits it is noted that while many larvæ spin a cocoon, others of the same species do not. The subject of polymorphism is discussed and the functions and status of the queen and workers compared with those of bees and wasps. After the nuptial flight, the males are allowed to die or are killed, while such females as may be found are brought back to the nest to add to the number of its queens. Various types of nests are described and cases cited where 2 colonies apparently nested together. Such cases may be mere accidental juxtaposition or it may be true association. There may be also double nests formed by 2 different kinds of ants, as where *Solenopsis fugax* makes its small galleries within the more massive walls of the nest of *Formica fusca* and steals and devours the latter's nymphs. There may be also genuine mixed colonies. Directions are given for making artificial nests, etc.

**The Embiidæ**, B. GRASSI (*Quart. Jour. Micros. Sci.* [London], n. ser., 40 (1897), pp. 55-75; abs. in *Jour. Roy. Micros. Soc.* [London], 1897, No. 5, p. 372).—As an appendix to his memoir on the termites the author gives the results of a study of this family of insects. The external features of the larvæ and adult male and female *Embia solieri* are described in detail. No trace of wings is found in either insect at any stage. The insects live in silken galleries which they construct under stones and in the ground underneath. The silk is extruded as a liquid from the anterior legs and the formation of a gallery takes from 12 to 15 hours time. The insects become adult

about the middle of June and pair at the end of the month and die off during the summer. An account is given of the internal anatomy of *Embia eurichii*. The Embiidae are regarded as interrelated neither with Termitidae nor Perlidae; nor do the authors think they have any relation with Psocidae. According to Grassi they should be ranked as a special suborder parallel with Orthoptera *sensu stricto* under the order Orthoptera. On the other hand the translator of Grassi's papers (which appeared in the original language in 1888-'89) regards them as occupying an intermediate position between Thysanura and cursorial Orthoptera.

**On *Cuterebra emasculator* with descriptions of several allied species**, D. W. COQUILLET (*Canad. Ent.*, 31 (1898), No. 1, pp. 9-11).—Five new species are described. They are distinguished by the abdomen being wholly polished, without powder, and with black pleural hairs (*Cuterebra tenebrosa*); by the same features except the pleural hairs, which are mostly yellow, there being only a small patch of black ones in the male (*C. nitida*); by the same characters as the last except the black patch of hairs, which is absent (*C. polita*); by the abdomen being partly opaque pollinose and by a cluster of black hairs above the center of the pleura, the rest being yellowing (*C. lepirova*); and by the same characters as the last except the black hairs, which are absent (*C. latifrons*). Fitch's type (specimen of *C. emasculator*) is stated to be identical with *C. fontinella* of Clark.

**The Cædemeridæ of boreal America**, G. H. HORN (*Proc. California Acad. Sci.*, 6 (1896), No. 2, pp. 382-421).

**The fauna of British India, including Ceylon and Burmah**, W. T. BLANFORD (*Published under authority of Secretary of State for India; rev. in Nature*, 56, No. 1451, pp. 363, 364).—The twelfth volume of this series. Bees and wasps are treated.

**Hymenoptera**, C. J. BINGHAM (*London: Taylor & Francis*, 1896, pp. XXIX, 579, pls. 4, figs. 188; *rev. in Nature*, 56, No. 1451, pp. 363, 364).—Volume 1, treating of bees and wasps.

**The production of sound by beetles**, S. SCHENKLING (*Illus. Wechschr. Ent.*, 2 (1897), No. 18, pp. 273-280, figs. 10).—The various methods of producing sounds are popularly discussed. Considerable space is given to stridulation in the different groups. The different heads are humming, knocking, clicking, shooting, and stridulating.

**On the building and keeping of an insectary**, O. SCHULTZ (*Illus. Wechschr. Ent.*, 2 (1897), No. 10, pp. 154-159).

**Essay on the general classification of the Lathridiidae, with a systematic and alphabetic catalogue of all the species of the world**, R. P. BELON (*Rev. Ent.*, 16 (1897), No. 6-7, pp. 157-220; 4-5, pp. 116-156).

**Report of the entomologist**, A. D. HOPKINS (*West Virginia Sta. Rpt.* 1891, pp. 59-64).—A report mostly on journeys about the State. Grasshoppers are noted as having appeared in the northern part of the State in considerable numbers; also the cabbage maggot along the Ohio River.

**Watering bees—a trough for the purpose**, J. C. COREY (*Amer. Bee Jour.*, 37 (1897), No. 8, p. 115, fig. 1).—For use in the more or less arid regions of the West, where bees must go a long way for water, the author's device seems excellent. It consists of a large trough made of a sheet of No. 22 galvanized iron 36 by 84 in. with the side turned up 5 in. high, so as to form a kind of immense dripping pan with a capacity of about 30 gal. In this a lath or cleated float, occupying the whole area, is placed, and pipe connection made with a source of water supply.

**Mating queens—how it may be controlled**, L. A. ASPINWALL (*Amer. Bee Jour.*, 37 (1897), No. 26, pp. 402, 403; *from Beekeepers' Review for January, 1897*).—Where one has thoroughbred bees at home, the clipping of the wings of the virgin queen so as to lessen somewhat her powers of flight is recommended.

**Comb foundation—is its use profitable?** S. A. DEACON (*Amer. Bee Jour.*, 37 (1897), No. 37, pp. 579, 580).—The author argues that the advantages claimed for foundation do not equal its cost. The only advantage that he is able to see is the exclusion of drone cells. It does not, as was once thought, take 20 lbs. of honey to

make 1 lb. of wax but only about 6; and, further, the process of wax formation goes on continually and when foundation is used the small scales of wax accumulate as rubbish on the floor of the hive.

Simmins is quoted as stating that 1 lb. of wax, costing less than 1 shilling 6 pence, fills 8 standard frames with finished comb. To do this with foundation, 1½ lbs. are required, costing at least 2 shillings 6 pence.

**The Danzen-Baker hive** (*Amer. Bee Jour.*, 37 (1897), No. 10, pp. 145, 146, figs. 10).—The main difference from the 10-frame Langstroth hive consists in the hive body being 1½ in. deeper and in the arrangement of the frames, etc. The brood frames are closed at the bottom, 7½ by 10 in. in size, and suspended upon a pivot in the middle of the end piece, which allows their being reversed. The super contains 8 holders of four 4 by 5 sections each. These sections are open-cornered—a device which, it is claimed, causes them to be filled out and to look better and bring as much as 2 cts. per pound more. The separators are of cleated slats. Outside of the sections is an air space and over them a layer of paraffin paper held down beneath and covered by several layers of newspapers. In the brood chamber there is also a dead air space about the frame.

**Tunis from the point of view of honey production**, T. B. BLOW (*Rev. Internat. Apicult.*, 19 (1897), No. 8, p. 139-142).—According to the author, in certain districts of Algiers rosemary (*Rosmarinus officinalis*) and heather (*Erica multiflora*) form much the most abundant forage plants and produce great quantities of honey of extra fine quality. They are succeeded by *Calicotome villosa*, *Thymus munidicus*, etc., and species of cistus. The average production of honey per colony is taken to be 25 kilos, which, for 1,000 colonies, worth 25,000 francs, and allowing 35 per cent for care and 15 per cent for interest, gives an annual profit of 50 per cent.

**Mosquitoes and fleas**, L. O. HOWARD (*U. S. Dept. Agr., Division of Entomology Circ. 13, 2. ser.*, pp. 5).—This is a revised edition (E. S. R., 8, p. 61). Since the publication of the original edition 9 species of mosquitoes have been noted as occurring within the United States, thus raising the number recorded to 30.

**The army worm and wheat fly**, C. B. WALDRON (*North Dakota Sta. Rpt. 1896*, pp. 20-22).—Notes that the army worm (*Leucania unipuncta*) did considerable damage in Pembina and Walsh counties during 1896; and also a general attack on wheat fields by an insect that is either the Hessian fly or frit fly. The latter insect has never been noticed in the State in such numbers as during 1896.

**Recent observations on the cecidomyid galls of the larches**, C. VON TUBEUF (*Forstl. Naturw. Ztschr.*, 6 (1897), pp. 224-229, figs. 2; *rev. in Zool. Centbl.*, 4 (1897), No. 26, p. 919).—Cecidomyid galls were found in the neighborhood of Munich on the flower buds of the larch. The morphological changes produced in the tissues were very peculiar.

**The contest with the phylloxera**, E. BUGNON (*Chron. Agr., Canton Vaud*, 9 (1896), No. 11, pp. 263-271).—Report from the Canton of Vaud to the Grand Council.

**The contest with the phylloxera in the Canton of Vaud in 1895**, J. DUFOUR (*Chron. Agr. Canton Vaud*, 9 (1896), No. 13, pp. 315-318).—During the year the insect was found in 4 new parishes. A total of 2,028 grape stocks were infested and a total area of 41,350 square meters destroyed.

**The phylloxera and American vines**, J. DUFOUR (*Chron. Agr. Canton Vaud*, 10 (1897), Nos. 12, pp. 331-337; 13, 370-373).—An extract from the report of the Viti-cultural Station at Lausanne for 1896. Among other things it is noted that the cost of visiting various vineyards aggregating 6,600 hectares amounted to about \$3,550, and required the services of 427 men; that 9 new places of infestation were discovered, and that the grape stocks attacked by the phylloxera numbered 11,958; and that 35,469 square meters of vineyard surface were destroyed.

Contrasting this with previous years, it is noted that in 1892, 839 grape stocks were attacked and 5,496 square meters of vineyard surface were destroyed; that these

numbers changed in 1893 to 14,144 stocks and 33,012 square meters; in 1894 to 3,800 stocks and 26,112 square meters; and in 1895 to 2,028 stocks and 41,350 square meters.

Combating peronospora and phylloxera, A. GAWALOWSKI (*Ztschr. Nahr. Unters. u. Hyg.*, 11 (1897), No. 16, pp. 271, 272).

The green scale of coffee, T. D. A. COCKERELL (*Gard. and Forest*, 10 (1897), No. 497, p. 347).—*Lecanium viridi*, the coffee scale of Ceylon, is recorded as having been found on coffee at São Paulo, Brazil, by Dr. von Ihering.

Biological notes on the pine worm, *Panolis piniperda*, H. GAUCKLER (*Illus. Wehnschr. Ent.*, 2 (1897), No. 14, pp. 213-215, figs. 3).—The feeding habits, etc., are described. In 1895 the larvæ appeared in great numbers in Hesse and did great damage to the pines. Near Lampertheim nearly all the 53-year old pines on about 24 hectares are now dead. In another area of 60 hectares near the same place most of the trees, which are almost 70 years old, are either dry or show but few green needles. The following parasites have been found affecting this insect: *Ichneumon molitorius*, *I. trilineatus*, *I. bilunulatus*, *I. raptorius*, *I. pallifrons*, *I. athiops*, *I. comitator*, *I. fabricator*, *I. metaxanthus*, *I. nigritarius*, *I. pinitorum*, *I. piniperde*, *Cryptus arrogans*, *C. filicornis*, *C. intermedius*, *C. leucostomus*, *C. longipes*, *C. seticornis*, *C. piniperde*, *Phygadeuon nigritarius*, *P. commutatus*, *Ophion ramidulus*, *O. luteus*, *O. meridarius*, *Anomalon unicolor*, *A. xanthopus*, *A. glisceus*, *A. biguttatum*, *Pimpla exinator*, *P. instigator*, *Heteropelma calcator*, and *Eurylobus tristis*.

Directions for collecting and preserving scale insects (Coccidæ), T. D. A. COCKERELL (*U. S. Nat. Mus. Bul.* 39, pt. 1, pp. 9).—The various places and countries where coccidological lists have been made are enumerated and also the countries that still offer fresh fields for the collector. The whole of the East Indian Archipelago, China, Siam, the Malay Peninsula, and Burmah have yet to be explored for coccidæ; also the whole of tropical Africa, the islands of the Indian Ocean, and Madagascar. It is shown that it is important to note the food plant from which scales are collected and brief directions for the recognition, collection, and treatment in the field and in the cabinet are given.

Destruction of the "pyrale" by washing with nitric acid, L. DEGRULLY (*Prog. Agr. et Vit.*, 28 (1897), No. 51, pp. 697-699).—The use of nitric acid against the "pyrale" (*Cenophtira pilleriana*) is described as effective and economical and is compared with a wash of sulphate of iron. It is diluted with 6 volumes of water. Thus diluted it is used at the rate of 25 liters of acid to 1,000 plants or 28 liters to 800 plants. At these rates the cost is about 42.37 cts. for the first and 53.77 for the second. Besides forming a good insecticide, the acid, on account of the nitrogen contained, is further commended as a manure. During winter the ground about the base of the vines may be sprayed with the acid, diluted to 1 to 6, as a remedy for the phylloxera.

Recent observations on the employment of nitric acid against the "pyrale," L. DEGRULLY (*Prog. Agr. et Vit.*, 28 (1897), No. 52, pp. 729, 730). It is noted that the penetrating qualities of nitric acid used according to the directions given in a preceding note are not as great as might be desired, and further, that it has not yet been determined whether the acid injures the plants.

A bee parasite, H. THEEN (*Illus. Wehnschr. Ent.*, 2 (1897), No. 16, pp. 242-247, figs. 8). The history, life history, etc., of *Meloe proscarabæus* is discussed.

A new parasite of the Harlequin cabbage bug, L. O. HOWARD (*Canad. Ent.*, 31 (1898), No. 1, pp. 17, 18).—*Encyrtus johnsoni*, n. sp., which is closely related to *E. nitratulus* of Europe, is described as obtained from eggs of *Murgantia histrionica* in Maryland.

On parasites of insects, K. SAJÓ (*Illus. Wehnschr. Ent.*, 2 (1897), No. 5, pp. 70-76).—A general paper noting among other things that the hosts of but few of the recognized parasitic species are known.

## FOODS—ANIMAL PRODUCTION.

**Human food investigations, H. SNYDER** (*Minnesota Sta. Bul. 54, pp. 37-90, figs. 5*).—*The gluten of wheat* (pp. 37-42).—The author points out that the value of flour for bread is dependent upon the total amount of gluten which it contains and upon the proportion of glutenin and gliadin making up the gluten. The total protein, gliadin, and glutenin in a number of samples of American and foreign wheat was determined. The gliadin was obtained by extracting finely ground wheat with 70 per cent alcohol. The glutenin was obtained by extracting with potassium hydroxid solution after first removing all other proteids. In the following table a number of varieties of wheat are compared on the basis of their content of nitrogenous constituents:

*Composition of the gluten of wheat.*

Variety of wheat.	Source.	Protein (N. + 5.7).	Proteids in gluten.	Gliadin.	Glutenin.	Gluten in form of—

“For bread-making purposes the gluten should be well balanced; that is, contain the right proportion of gliadin (binding material) to glutenin. The most valuable wheats for both food and bread-making purposes are those rich in protein, of which 80 to 85 per cent is gluten, and the gluten is composed of about 60 per cent gliadin and about 40 per cent glutenin. . . . In the samples [of Scotch Fife and Wellman Fife], which may be taken as good types of northern-grown hard spring wheat, the gluten contains about 60 per cent gliadin and 40 per cent glutenin. In the so-called soft wheat [Blue Stem Calcutta and Oregon White Winter] there is from 7 to 13 per cent more of gliadin and a correspondingly less amount of glutenin.”

Bread was made from (1) flour from which the gliadin had been extracted, (2) flour from which the albumin had been extracted, (3) flour from which proteids soluble in sodium chlorid solution had been extracted, and (4) normal flour. In the first case “the dough was not sticky; it felt like putty and broke off like putty. The yeast caused the mass to expand a little when first placed in the oven, then the top of the loaf began to break apart, and the loaf decreased in size as if no yeast had been used. The loaf, when baked, was about as heavy as the same bulk of rubber.” In the second and third cases the bread

did not differ materially from that made from normal flour. "The gliadin and glutenin are the only proteids which give character to bread; that is, provided the bread is properly made."

*The digestibility of bread* (pp. 43-45).—Experiments were made with a man to learn the digestibility of bread made from the best grade of patent spring-wheat flour, from ordinary bakers' flour, and from whole-wheat flour. The subject of the test weighed about 150 lbs., and on each day walked about 4 miles for exercise. About 1½ lbs. of bread, ½ lb. of butter, and ½ lb. of eggs were eaten daily. The author calculates that if the bread were purchased from a baker the cost of a day's food would be 15½ cts., and if the bread were made at home the cost would be about 10 cts. The flour used was analyzed and its composition is reported. In the author's opinion the whole-wheat flour was of an inferior quality. It was purchased as high-grade flour, but had apparently been made from winter wheat deficient in protein. The coefficients of digestibility of the different kinds of bread are shown in the following table:

*Coefficients of digestibility of bread.*

	Dry mat- ter.	Protein.	Fat.	Carbohy- drates.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Bread from patent flour.....	94	86	87	97
Bread from bakers' flour.....	93	84	87	97
Bread from whole-wheat flour.....	93	87	86	97

*Composition of bread* (pp. 46, 47).—Assuming that bread should be selected for its protein content, the author discusses that made from ordinary flour and from whole-wheat flour. An unfermented bread, which is quite extensively used in many parts of Minnesota under the name of "flat bread," is described. It is made from whole-wheat flour or ordinary flour and baked in the form of large, flat, round cakes. The dough is sometimes rolled very thin before baking. Samples of flat bread made from whole-wheat flour and patent flour were found to have the following composition:

*Composition of flat bread.*

	Water.	Protein.	Fat.	Carbohy- drates.	Ash.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
From whole-wheat flour .....	9.38	15.50	0.70	72.92	1.50
Do .....	9.03	15.63	.60	72.64	1.50
From patent flour.....	10.54	13.44	.20	75.28	.54

*The loss of food value by prolonging fermentation in bread making* (pp. 48-51).—Seven tests were made to study the loss of material due to fermentation in bread making. The bread was made according to 2 methods in common use. In 3 trials the short fermentation method was followed. A dough was made of flour, water, and yeast, which was kneaded

thoroughly and allowed to rise until it had doubled its bulk, when it was again kneaded and allowed to rise, and then baked. In 4 trials the fermentation was more prolonged. A batter was made from flour, yeast, and water and allowed to ferment over night, usually 10 to 15 hours. More flour was then added, the dough was kneaded and allowed to rise a second time. It was then treated as by the first method. By the second method a much smaller quantity of yeast was used than by the first method and the fermentation was carried on at a lower temperature. The flour, yeast, and bread were weighed and analyzed and the results are tabulated. All the flour used was from the same lot of patent flour made from hard spring wheat.

"When the bread was made by the short fermentation process, there was a loss of 1.74 per cent of dry matter, equivalent to a loss of a little more than 3 lbs. of flour per barrel. When the bread was made by the prolonged fermentation process there was a loss of 8.08 per cent of dry matter, equivalent to a loss of about 11½ lbs. of flour for every barrel of flour used.

"When the bread was made by the short fermentation process there was an average loss of 2.10 per cent of the total nitrogen; with the prolonged fermentation process the loss of nitrogen was 7.77 per cent. When a barrel of flour is made into bread by the prolonged fermentation process, the loss of nitrogen exceeds the loss by the short fermentation process in protein value equal to about 7 lbs. of the best sirloin steak."

*The digestibility of potatoes and losses of food values when potatoes, carrots, and cabbages are boiled in different ways* (pp. 52-57).—This is a brief account of work reported in Bulletin 43 of this Office (E. S. R., 9, pp. 677, 679).

*The rational feeding of men* (pp. 60-90).—The author summarizes in a general way the results of numerous investigations, and briefly discusses the general laws of nutrition. The composition of a large number of foods and the amounts and composition of different foods which can be purchased for 10 cts. are quoted.

**Studies of dietaries**, W. O. ATWATER and A. P. BRYANT (*Connecticut Storrs Sta. Rpt. 1896, pp. 117-158*).—This is a continuation of work previously reported by the station (E. S. R., 8, p. 419). The results of 9 dietary studies hitherto unpublished are reported in full. A summary follows:

*Results of dietary studies—food eaten per person daily.*

	Cost.	Protein.	Fat.	Carbohy- drates.	Fuel value.
	<i>Cents.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Calories.</i>

*a* The figures represent the quantities purchased.

The results of previous studies reported by the station are quoted, and from them and the above studies a number of averages are deduced.

**Dietary study of Sandow, the "strong man,"** C. F. LANGWORTHY and W. H. BEAL (*Connecticut Storrs Sta. Rpt. 1896, pp. 158-162*).—The food consumed in a day by Sandow, the professional "strong man," was weighed and its composition calculated. The nutrients consumed were protein 244 gm., fat 151 gm., and carbohydrates 502 gm. The energy of the food was calculated to be 4,462 calories. The nutritive ratio was 1:3.4.

"It will be seen that while the amount of carbohydrates and fat consumed does not differ very greatly from the standard for a man at muscular work, the amount of protein is very large and the nutritive ratio is very narrow.

"The fact that so much protein is consumed is of especial interest."

**The digestibility of different classes of food materials,** W. O. ATWATER (*Connecticut Storrs Sta. Rpt. 1896, pp. 186-190*).—On the basis of results of a large number of digestion experiments made by different investigators, the author deduces the following average coefficients of digestibility for animal foods, cereals and sugars, and vegetables and fruits:

*Average coefficients of digestibility.*

	Protein.	Fat.	Carbo- hydrates.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Animal foods.....	98	97	100
Cereals and sugars.....	85	90	98
Vegetables and fruits.....	80	90	95

The coefficients of digestibility of protein, fat, and carbohydrates as actually determined by the author in the experiments with man cited below were compared with the above calculated results for the same food materials. The agreement was found to be very close, as is shown by the following table:

*Comparison of determined with average coefficients of digestibility.*

	Protein.	Fat.	Carbo- hydrates.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
As found by experiment.....	93.7	95.3	97.7
As calculated.....	94.0	96.3	98.1

"This close agreement implies that the assumed coefficients fairly represent the proportions of nutrients that are digested, under ordinary normal conditions, from such food materials as those used in these experiments."

**Experiments on the digestion of food by man,** W. O. ATWATER (*Connecticut Storrs Sta. Rpt. 1896, pp. 163-180*).—A number of digestion

experiments with single food materials and a mixed diet were made under the direction of the author by the usual methods, which have been described in detail in a previous publication.<sup>1</sup>

The fuel value of the food, urine, and feces was determined. The fact is pointed out that the fuel value of the food minus the fuel value of the feces does not represent the energy which is available for the organism, since nitrogen is excreted in the form of urea.

"Assuming that all of the digested nitrogen excreted from the body is in the form of urea, we may roughly calculate the amount of the potential energy of protein which thus fails to be transformed into kinetic energy in the body.

"Urea contains 46.67 per cent nitrogen, hence  $N. \times 2.143 = \text{urea}$ .  $N. \times 6.25 = \text{protein}$ . Hence protein divided by  $6.25 \times 2.143 = \text{the urea corresponding to the protein}$ . The heat of combustion of 1 gm. of urea is 2.53 calories. The fuel value of the urea corresponding to 1 gm. of protein would therefore be  $\frac{1}{6.25} \times 2.143 \times 2.53$ , or 0.87 calories.

"According to this computation, which is theoretical and but approximately correct, there would be for each gram of digested protein 0.87 calories of energy in the unconsumed urea and other compounds. Subtracting this value from the total fuel value of the digested nutrients the remainder may be assumed to represent the proportion of the total energy of the digested nutrients which becomes actually available to the body. This is designated in the tables as 'net fuel value of the food digested.'"

The results of the experiments are briefly shown in the following table:

*Coefficients of digestibility of a number of foods by man.*

Subjects and food materials.	Protein.	Fat.	Carbohydrates.	Net fuel value.
<i>Laboratory janitor.</i>				
Milk.....	88.1	97.0	84.4	87.8
Do.....	90.9	95.5	85.0	89.4
Do.....	95.6	98.1	89.5	89.3
Wheat bread.....	91.9	.....	99.4	94.6
Do.....	82.3	.....	98.7	92.4
Bread and milk.....	97.6	98.9	98.9	95.2
Beef round, milk, butter, oatmeal, bread, sugar.....	94.4	96.7	98.5	93.3
Beef round, eggs, butter, cheese, milk, crackers, bread, potatoes, sugar.....	95.9	97.4	97.9	93.2
Do.....	91.8	97.1	98.4	92.6
<i>Chemist.</i>				
Beef round, eggs, butter, milk, bread, potatoes, apples, peaches, pears, sugar.....	94.9	96.9	98.9	94.1
<i>Physicist.</i>				
Beef round, butter, milk, white bread, brown bread, oatmeal, beans, potatoes, apples, sugar.....	91.3	95.9	97.7	96.9
<i>Three chemists.</i>				
Mixed diet (meat, eggs, bread, vegetables, fruit, etc).....	91.1	96.2	99.2	94.6

"The results of the first 5 experiments are not entirely reliable indications of the actual digestibility of milk and bread as ordinarily eaten, partly because of defects in the experiments themselves, and partly because of the probability that these materials, taken by themselves, are not digested as completely as when they form a part of a mixed diet. . . .

<sup>1</sup> U. S. Dept. Agr., Office of Experiment Stations Bul. 21 (E. S. R., 7, p. 148).

"As regards the variations of digestion of food by the same person under different conditions, the results of inquiry up to the present time lead to the inference that while the digestive apparatus of the subject is in normal condition, and the quantities of food are also normal, the coefficients of digestibility are much less affected by exercise or rest than is commonly supposed. There does seem to be ground, however, for the belief that in ordinary mixed diet the digestion is generally more complete than where only a single food material is eaten."

The digestion experiment with 3 chemists was made in connection with a dietary study published in the Annual Report of the station for 1894 (E. S. R., 7, p. 596). The balance of income and outgo of nitrogen was determined for each of the 10 days of the experiment. The average daily balance was as follows: In food 18.5 gm., in urine 11.9 gm., in feces 1.7 gm.; nitrogen gained 4.9 gm., protein gained 30.7 gm.

"It will be noticed that protein was stored constantly during the experiment, showing that the dietary furnished more of total nutrients and of nitrogenous material than was necessary for nitrogen equilibrium under the circumstances.

"The amounts of food eaten varied from day to day in accordance with the inclinations of the subjects of the experiments. This doubtless explains in large part the daily variations in the nitrogen excretion."

**Two digestion experiments with an infant, A. P. BRYANT** (*Connecticut Storrs Sta. Rpt. 1896, pp. 181-185*).—Two digestion experiments with an infant were made in connection with dietary studies previously reported by the station (E. S. R., 8, p. 419). In the first test the food consisted of cows' milk alone and in the second of cows' milk, oatmeal, and sugar. The child was about 9 months old. The results are briefly shown in the following table:

*Coefficients of digestibility of milk and milk, oatmeal, and sugar.*

	Total organic matter.	Protein.	Fat.	Carbo-hydrates.	Ash.	Available fuel value.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Milk.....	91.5	93.8	95.7	83.3	51.6	86.3
Milk, oatmeal, and sugar.....	95.6	95.3	98.4	93.7	60.9	91.0

The results obtained are discussed at length and compared with similar results obtained by other investigators.

"It may be of interest to note here that a rough qualitative test showed but a comparatively small amount of calcium salts and of phosphoric acid in the feces, while the ash of the milk and of the oatmeal contained these substances in relatively large amounts."

**The influence of borax and boric acid upon nutrition, with special reference to proteid metabolism, R. H. CHITTENDEN and W. J. GIES** (*Amer. Jour. Physiol., 1 (1898), No. 1, pp. 1-39*).—The authors report 3 experiments with a dog. A period in which borax or boric acid was given was preceded and followed by a normal period. The balance of income and outgo of nitrogen was determined; also the specific gravity of the urine, its reaction, and content of uric acid, total and

combined sulphur, and total phosphoric acid. The principal conclusions reached were as follows:

Moderate doses of borax, up to 5 gm. per day, were continued for some time without influence on proteid metabolism, while doses, 5 to 10 gm. daily, had a direct stimulating effect. Boric acid, in doses up to 3 gm. per day, was practically without effect on proteid metabolism and the general nutrition of the body. Large doses of borax tended to retard the assimilation of protein and fat, increasing noticeably the weight of the feces and their nitrogen and fat content. Boric acid, on the contrary, in doses up to 3 gm. was without direct influence in this regard. Borax and boric acid are quickly eliminated from the body through the urine, 24 to 36 hours being generally sufficient for the purpose. They are rarely found in the feces. Neither has any influence on the putrefactive processes in the intestines. No abnormal symptoms in the urine were observed, neither sugar nor albumen being found. Owing to their rapid elimination no marked accumulative effect can result from the daily consumption of borax and boric acid in moderate quantities.

These experiments are of importance, in view of the fact that borax and boric acid are used as food preservatives.

**Digestion experiments with sheep,** C. S. PHELPS and A. P. BRYANT (*Connecticut Storrs Sta. Rpt. 1896, pp. 246-272*).—This is an account of work in continuation of that reported in the Annual Report of the station for 1895 (E. S. R., 8, p. 422). Eighteen experiments are reported. They were made by the usual methods followed at the station. The results are briefly given in the following table:

*Average coefficients of digestibility of feeding stuffs.*

	Number of tests.	Organic matter.	Protein.	Fat.	Nitrogen-free extract.	Fiber.	Ash.	Fuel value available.
		<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>
Field-cured clover rowen .....	2	59.3	62.7	59.4	63.6	49.1	44.1	53.8

*a* Fed green.

**The action of certain bodies on the digestive ferments,** F. D. SIMONS (*Jour. Amer. Chem. Soc., 19 (1897), No. 9, pp. 744-755*).—The author reports a number of experiments on the effect of picric acid,

tropaeolin 000, metanil yellow, Bismarck brown, cinnamon (10 parts oil of cinnamon and 90 parts alcohol), formol, salicylic acid, wintergreen, peppermint, chrysoidin, saffranin, and methylene blue on pancreatic and peptic digestion. Different quantities of the several substances were added to solutions of peptic and pancreatic ferments and the effect on digestibility of albumen was observed. It was found that picric acid, tropaeolin 000, and metanil yellow hindered peptic digestion; Bismarck brown, cinnamon, and formol hindered pancreatic digestion; wintergreen and salicylic acid partially arrested peptic digestion; and peppermint, chrysoidin, saffranin, and methylene blue had no apparent effect on the action of either of the ferments.

**Silage for hogs**, D. O. NOURSE (*Virginia Sta. Bul.* 68, pp. 101-105).—Two tests were made to study the value of silage in a maintenance ration for pigs. The first was made with 2 lots of sows. Lot 1 consisted of a Poland-China and a Berkshire, and lot 2 of 2 Poland-Chinas. The pigs in lot 1 were fed per week  $17\frac{1}{2}$  and 14 lbs., respectively, of corn on the cob. Those in lot 2 were fed 56 and 49 lbs. of silage per week, respectively. Some of this (about 10 lbs.) was wasted, but the amount was not accurately determined.

During the 7 weeks of the test lot 1 lost 3.5 lbs. and lot 2 27 lbs. The pigs were in poor condition at the close of the test. Reckoning silage at \$2 per ton and corn at 35 cts. per bushel, the silage was much the cheaper food. The animals were fattened after the close of the test, and no difference was observed in the 2 lots.

In the second test the value of silage as part of a ration was studied. A boar and a sow were each fed about 21 lbs. of corn on the cob and 35 lbs. of silage per week; another sow was fed 14 lbs. of corn on the cob and 28 lbs. of silage. During the 10 weeks of the test the boar lost 18 lbs., and the sow fed the same ration lost 6 lbs., while the sow fed the smaller ration gained 13 lbs. The pigs appeared in good condition.

On the basis of the values mentioned above the pecuniary value of silage is discussed. "So far as the above results are concerned, we should say silage was economical to use in conjunction with corn as a maintenance ration, but not so if used alone."

**Feeding experiments with chickens**, T. D. HINEBAUGH (*North Dakota Sta. Rpt.* 1896, pp. 16-18).—Brief statements are made concerning the condition of the poultry department at the station.

A test was made to determine whether heating a poultry house diminished the cost of feeding and increased the egg production. Forty-six chickens were fed in an unwarmed poultry house from December 1 until January 20. At the beginning of the test they were fed 5 lbs. of table scraps in the morning and 2 lbs. of wheat screenings at night. Afterwards the ration was increased until they consumed  $11\frac{3}{4}$  lbs. of scraps in the morning and  $11\frac{1}{2}$  lbs. of wheat screenings in the evening.

From January 20 until March 31 the poultry house was heated by means of a stove. At the end of January only 6 lbs. of scraps were consumed in the morning and  $8\frac{3}{4}$  lbs. of screenings in the evening. At the close of the test the morning ration consisted of  $4\frac{1}{2}$  lbs. of table scraps, and the evening ration of  $4\frac{3}{4}$  lbs. of wheat screenings. The total cost of the fuel was \$4.50.

During the month of January, before the artificial heating was begun, the average number of eggs produced was  $2\frac{3}{4}$  per day, and during the remainder of the month the average was  $6\frac{2}{11}$ . That is, when the poultry house was heated about half as much food was consumed and the egg production was more than doubled. With eggs at 25 cts. a dozen and food at the usual price, heating the poultry house proved profitable.

A second test extending from December 1 to June 1 was made with 2 lots of pullets to compare rations for laying and breeding stock. Lot 1 consisted of 16 and lot 2 of 19 pullets. Both lots were fed under the same conditions of temperature, housing, etc. Lot 1 was intended for breeding, and it was therefore desirable that they should not lay until late in the season, and that the egg production should then be regular. They were fed wheat screenings and corn. Lot 2 were fed for egg production, it being desirable that as many eggs should be produced as early in the season as possible, while the price was high. The pullets in this lot were given boiled lean meat and scraps from the table from which the fat had been removed. At night they were fed wheat screenings *ad libitum*, and twice a week corn was fed in addition. Water was supplied in abundance. The wheat screenings used in this test were of a better quality than those fed lot 1.

At the end of March it was desired that lot 1 begin to lay for breeding purposes, and from this time until the close of the test they were fed a ration similar to that fed lot 2. The egg production of lot 1 by months was as follows: December, 0; January, 7; February, 12; March, 43; April, 189; and May, 381. The average per pullet for the whole test was 150.5 eggs. Before the rations were changed the pullets had the appearance of being over fat.

The egg production of lot 2 by months was as follows: December, 63; January, 124; February, 109; March, 168; April, 129; and May, 142. The average per pullet for the whole test was 153 eggs.

The eggs produced during the earlier part of the season sold for a higher price than those produced later.

**Bread making**, MARIE B. SENN (*North Dakota Sta. Rpt. 1896, pp. 43-46*).—A number of experiments were made and the amount of flour required of different sorts with a definite quantity of yeast, etc., was recorded. The other ingredients remaining the same, the amount of flour necessary for making bread varies with its gluten content.

**The pure food question in Pennsylvania**, L. WELLS (*Pennsylvania Dept. Agr. Bul. 3, pp. 37*).—A discussion of the manufacture and sale of oleomargarin and other adulterated food products, with text of laws and decisions of the Supreme Court of the State of Pennsylvania pertaining thereto.

**Pure food and dairy laws of Pennsylvania**, L. WELLS (*Pennsylvania Dept. Agr. Bul.* 32, pp. 25).—A summary of the several acts of the Assembly relating to foods and dairy products, with decisions of the courts in regard to the same.

**Subsistence and messing in European armies**, J. R. WILLIAMS, C. DE W. WILCOX, C. REICHMANN, and L. C. SCHERER (*War Dept. [U. S.], Adj. Gen. Office, Mil. Infor. Div.*, 16, 1, pp. 91).—A compilation of information concerning the food in times of peace and war of the armies of Austria, Belgium, England, France, Germany, Holland, Italy, and Switzerland.

**Soy beans as food for man**, C. F. LANGWORTHY (*U. S. Dept. Agr., Farmers' Bul.* 58, pp. 20-23).—Soy beans as food for man are discussed with special reference to the food preparations made from them in China and Japan.

**The average composition of American food materials**, W. O. ATWATER (*Connecticut Storrs Sta. Rpt. 1896*, pp. 190-198).—This is a condensation of Bulletin 28 of this Office (E. S. R., 8, p. 126).

**Analyses of fodders and feeding stuffs**, W. O. ATWATER and F. G. BENEDICT (*Connecticut Storrs Sta. Rpt. 1896*, pp. 273-287).—In connection with the work of the station during the year analyses were made of the following feeding stuffs: Timothy (*Phleum pratense*), orchard grass (*Dactylis glomerata*), meadow fescue (*Festuca elatior*), brome grass (*Bromus inermis*), red top (*Agrostis vulgaris*), millet fodder, cowpea fodder, oat fodder, oat and pea fodder, rowen, sweet corn fodder, soy bean fodder, corn silage, corn stover, clover hay, clover rowen, meadow-grass hay, millet and Hungarian hay, oat hay, swamp hay, yellow and white flint corn, oats, corn meal, Buffalo gluten feed, Chicago gluten feed, linseed meal, wheat bran, and wheat middlings.

**Proportions of digestible nutrients in food materials**, W. O. ATWATER (*Connecticut Storrs Sta. Rpt. 1896*, pp. 199-204).—Using the coefficients of digestibility noted (see p. 780) the digestible nutrients in a large number of American food materials were calculated.

**Investigations on metabolism in the human organism**, W. O. ATWATER, C. D. WOODS, and F. G. BENEDICT (*Connecticut Storrs Sta. Rpt. 1896*, pp. 85-116).—This is an account of experiments which were reported in Bulletin 44 of this Office, and are also briefly mentioned in E. S. R., 8, p. 821.

**Proceedings of the first convention of the Society for the Rational Feeding of Farm Animals** (*Compt. Rend. 1er. Congrès Soc. Aliment. Rat. Bétail, 1897*, pp. 136).—In addition to a report of the routine business, there are included papers by a number of investigators on animal production and feeding of young animals; the feeding of draft animals, dairy cows, and animals for market; the toxic properties of certain feeding stuffs; methods useful in practical experiments in feeding animals; and the adulteration of feeding stuffs.

**The relation between the rate of growth of the young of different mammalia to the composition of milk**, F. PRÜSCHER (*Ztschr. Physiol. Chem.*, 24 (1897), No. 3, pp. 285-302).

**Studies on the hornless cattle of North Europe, with special reference to the North Swedish Fjell cattle, together with investigations on the cause of loss of horns**, E. O. AREXANDER (*Ber. Physiol. Lab. Landw. Inst. Halle*, No. 13, pp. 43-184, pls. 6, map 1).

## DAIRY FARMING—DAIRYING.

**A study of rations fed to milch cows in Connecticut**, W. O. ATWATER and C. S. PHELPS (*Connecticut Storrs Sta. Rpt. 1896*, pp. 53-84).—This is a report of the fourth winter's work on this subject (E. S. R., 8, p. 430), together with a summary of the results previously obtained.

Two herds of 11 and 13 cows, respectively, were tested for 12 days with reference to the food eaten and the milk and fat produced, and then in a transition period of 9 days a change was made to a more

nitrogenous ration, suggested by the station, and the herds tested for a second period of 12 days. Full data for the tests are given, from which the following summary is taken:

*Original and suggested rations fed to cows on 2 farms in Connecticut.*

Herd.	Ration.	Average daily ration per 1,000 lbs. live weight.				
		Digestible protein.	Digestible fat.	Digestible carbohydrates.	Nutritive ratio.	Fuel value.
		Pounds.	Pound.	Pounds.		Calories.
A	{Original .....	1.84	0.72	14.99	1:9.0	34,350
	{Suggested .....	2.93	.64	13.02	1:4.9	32,400
B	{Original .....	3.13	.72	15.94	1:5.6	38,500
	{Suggested .....	3.66	.97	14.21	1:4.5	37,350

"The total cost of the ration [of herd A] remained practically the same, but the net cost was greatly reduced in the second test, owing to the higher value of the manure. The average daily yield of milk was increased during the second test 0.7 lb. and the butter 0.05 lb. over that obtained in the first test. The total cost of feed to produce 100 lbs. of milk was reduced 4 cts. and the cost of feed for a pound of butter was reduced 2 cts. in the second test. . . .

"The total cost of each of the rations [of herd B] was large, although the second ration was slightly less expensive than the first. Quite a number of cows in the herd were well along in the period of lactation, and were no doubt being fed too heavily for the amount of product they were giving."

The results of the previous studies on the rations of cows on dairy farms are summarized, making 38 rations in all. Of these, 29 "actually represent the feeding practice of these dairymen." The minimum, maximum, and average nutrients of these 29 rations are given below, together with feeding standards.

*Rations fed by 29 Connecticut dairymen, and feeding standards.*

	Organic matter.	Digestible protein.	Digestible fat.	Digestible carbohydrates.	Fuel value.	Nutritive ratio.
	Pounds.	Pounds.	Pounds.	Pounds.	Calories.	
Rations of 29 Connecticut dairymen:						
Minimum .....	20.5	1.35	0.56	10.47	28,600	1:4.5
Maximum .....	33.7	3.48	1.36	18.25	42,600	1:11.3
Average .....	25.5	2.36	.87	13.76	33,650	1:6.7
Woll's average of 128 American rations.	24.5	2.15	.74	13.27	31,250	1:6.9
Ration tentatively suggested by Storrs Station .....	25.0	2.50	(.5 to .8)	(13 to 12)	31,000	1:5.6
Wolf's (German) standard .....	24.0	2.56	.40	12.5	29,600	1:5.4
Lehmann's (German) standards (a) for cows giving—						
11 lbs. of milk per day .....	25.0	1.60	.30	10.0	22,850	1:6.7
16½ lbs. of milk per day .....	27.0	2.00	.40	11.0	25,850	1:6.0
22 lbs. of milk per day .....	29.0	2.50	.50	13.0	30,950	1:5.7
27½ lbs. of milk per day .....	32.0	3.30	.80	13.0	33,700	1:4.5

aMentzel and von Lengerke's Landw. Kalender, 1897.

In 9 of the 38 rations studied there is opportunity for comparing a wide ration with a narrower ration fed to the same herd, the narrower ration being fed from 1 to 4 weeks after the wide ration, so that the cows were somewhat further advanced in the period of lactation. The data for these 9 comparisons are summarized.

"There was an increase in milk flow in 5 cases when the animals were fed a narrow ration over that obtained with the wider ration, and in 2 other cases the yields were essentially the same in both tests, although in those instances the narrow ration was fed 4 weeks after the wide. Of the 8 herds which were fed the wide ration followed by a narrower one all except one gave an increase in butter yield during the second test. The fact that there was more often an increase in butter yield (calculated from the butter fat) than in the milk yield, during the period when the narrow rations were fed, would indicate an increase in the percentage of fat as a result of using the narrow rations. In some instances this was noticeably the case. . . . There are 6 cases where the total cost of producing 100 lbs. of milk is less with the narrower ration, and 6 cases where the cost of 1 lb. of butter is less. . . .

"Although a shrinkage in production would naturally follow from advancement in period of lactation, the herds as a whole more than held their own when changed to the narrower ration from 1 to 4 weeks after the first test. The results are in accord with observation and experiment elsewhere in that so far as physiological effects are concerned narrow (nitrogenous) rations give larger yields of both milk and butter than do wide (carbonaceous) rations."

**Contribution to the rational feeding of cows,** O. HAGEMANN (*Landw. Jahrb., 26 (1897), No. 4-5, pp. 555-636*).—This is a continuation of the investigations, the account of the first part of which was published about 2 years ago (*E. S. R., 7, p. 237*). As previously stated, the author holds that, in order to draw reliable deductions as to the relative value of feeding stuffs for cows, experiments on the digestibility and the metabolism of the food should be made.

The present investigations covered 12 periods, about a year and a half, and most of the time included 2 cows, although 5 cows were used in all. A variety of grain and concentrated feeding stuffs were studied in combination with other materials. Very complete data were secured as to the amount and composition of the food, urine, feces, and milk, and the live weight; and from these data the digestibility of the food, nitrogen and ash balances, etc., were adduced. The full data for the experiments are tabulated, and the author gives considerable space to a discussion of his method of work and of the results of the experiments. He notes the scarcity of data on the labor of digestion in cattle. This can only be determined by respiration experiments and without this the carbon balance can not be calculated. He believes it probable that rations containing large amounts of starchy material, as corn, rye, barley, with small amounts of hay and straw, require a much smaller amount of labor for digestion than rations containing hay and straw together with oil cakes rich in albuminoids.

During the corn period with cow No. 3 and one of the rye periods with cow No. 2 there was a nitrogen loss, although both cows were producing large quantities of milk, but in all other periods nitrogen was stored in the body. In these periods also there was a small loss of ash constituents. The milk production appeared to be, to a certain extent, dependent upon the feeding. It did not depend alone upon large quantities of albuminoids in the food, as is usually stated, but also on other constituents.

Cow No. 1 showed fluctuations in the milk yield which could only be accounted for by the feed. When, in the twentieth week of lactation, corn was substituted for rye as the chief grain the average daily milk yield increased 2.52 kg., or 26 per cent, and the milk contained 3.52 per cent of fat as compared with 3.26 per cent in the preceding and following periods. The corn ration contained more digestible crude protein but less albuminoids than the rye ration. In the following period when wheat bran was fed in place of the corn more crude protein was digested and the total nutrients were larger, but the daily milk yield fell off 1.51 kg. and the fat content dropped to 3.26 per cent. A mixture of rye and palm cake proved advantageous, as it nearly maintained the yield of milk and increased the fat content from 3.09 to 4.51 per cent. A ration containing poppy cake, in spite of its higher content of digestible protein and total nutrients than rations of cotton-seed meal and of peanut cake, resulted in a falling off in the daily milk yield of 1.6 kg. in 3 weeks, while on the cotton-seed-meal ration the decrease was 1.48 kg. in 4 weeks. The poppy cake is consequently less valuable than the other oil cakes.

Cow No. 2, which during 4 weeks on the peanut-cake ration shrunk 0.88 kg. in daily milk yield, shrunk only 0.31 kg. during 2 weeks on cotton-seed meal. In the following period, on poppy cake, there was a much larger shrinkage in milk and a material decrease in the percentage of fat (from 3.15 per cent on cotton-seed meal to 2.51 per cent on poppy cake). Later, after this cow had calved, a rye ration was fed, on which, in spite of only about half the amount of digestible protein, a milk yield of 15.45 kg. with 2.93 per cent of fat was maintained. The author infers from this that the milk secretion depends first of all upon the condition of the milk glands.

Cow No. 3 had received a malt-sprout ration previous to the experiment, on which she produced 10.5 kg. of milk. Four weeks later (in the seventeenth week of lactation), on a corn-meal ration, she produced 11.32 kg. of milk—an increase of 0.82 kg.—although the amount of albuminoids was relatively small (330 gm.). In the following period, in which wheat bran was fed, there was a shrinkage of 1.32 kg. in milk, although almost exactly the same amount of total nutrients and over 100 gm. more of albuminoids were contained in the daily ration.

In the experiment with cows 4 and 5 the intention was to test the effect of feeding beet molasses to both cows, but No. 4 refused to eat the molasses. A ration of barley meal and palm cake was compared with one of palm cake and molasses. On the molasses there was a shrinkage of 2.42 kg. in the daily milk yield, but an increase of 0.3 per cent in the fat content. In the following period, when the barley meal and palm cake were fed, the yield increased 1.9 kg., but the fat content diminished. The protein in the molasses ration was relatively low. The excretion of urine in this period increased from about 14 liters to

20 liters per day. The author believes it probable that continued feeding of large amounts of molasses would have an injurious effect on the heart and the kidneys.

The discussion of the mineral balance is reserved for a special article. From the results of these investigations the author draws the following conclusions:

(1) The feeding of corn is in every respect advantageous to milch cows in the production of milk and the maintenance of live weight. Following this, wheat bran, cotton-seed meal, and peanut cake range in value in the order given.

(2) Poppy cake appears to diminish the percentage of fat in the milk and to be in general inferior for milk production to the other feeding stuffs tested.

(3) Beet molasses appears to have a stimulative action on the milk glands, so that for a time more and richer milk is yielded than on rations richer in total nutrients and in albuminoids.

**The cost and feeding value of the dry matter of dried corn fodder and of silage, E. B. VOORHEES and C. B. LANE** (*New Jersey Stas. Bul. 122, pp. 16*).—Twelve acres of a 15-acre field of corn was cut and placed in the silo the first week in September and the remaining 3 acres were shocked in the field and carted to the barn early in October. The cost of handling the silage and the corn fodder is given. Observations were made on the amount of silage lost in the silo by molding, etc., and analyses were made of the fodder and silage at different times.

“The changes that took place in the silo resulted chiefly in a change in the proportion of fiber and nitrogen-free extract, though a slight increase was noticed in the content of ether extract. The determination of the albuminoids showed that 98 per cent of the protein in the green fodder was in the form of albuminoids, and that 95 per cent was in that form in the dried fodder at time of storage, and when the dried fodder was fed 89 per cent was in that form—that is, relatively slight changes had taken place in this compound; whereas in the silage the albuminoids constituted but 37.5 per cent of the total protein as compared with 98 per cent when put into the silo. In drying fodder, therefore, the changes due both to mechanical and chemical causes resulted in an increase of woody fiber and a decrease in protein and nitrogen-free extract, and did not seriously affect the character of the nitrogenous matter, whereas in the silo the chemical changes resulted chiefly in a small loss only of nitrogen-free extract and in a very marked change in the protein, causing a serious loss of albuminoids. These results confirm conclusions already reached, particularly concerning the loss of albuminoids in the silo.”

A feeding experiment was made with 2 lots of 4 cows each to compare the silage and dry corn fodder. The lots were fed for a period of 12 days, one on the silage and the other on the corn-fodder ration, and then in a transition period of 5 days were reversed and the feeding continued for 12 days. The plan was to furnish the same amounts of dry matter in the 2 rations, one-half of this being in the form of either corn fodder or silage; but this was found to be impracticable, as the animals ate more of the silage than of the corn fodder. They ate the grain and finer parts of the corn fodder, but left the coarser parts.

The amount of nutrients consumed in each period and the yields of milk and of fat are tabulated.

Lot 1, which received corn fodder first, gave practically the same yield of milk and of fat in both periods; but lot 2, which received silage first, showed a marked falling off in yield of both milk and fat in the dried fodder period. Combining the yields of the 2 lots on silage and on dried corn fodder to neutralize any effect of advancing lactation gives the following:

*Milk and fat produced and food consumed on silage and dried corn-fodder rations.*

	Total yield of milk.	Average fat content of milk.	Total yield of fat.	Digestible food eaten.			
				Total dry matter.	Protein.	Fat.	Carbohydrates.
	Pounds.	Per cent.	Pounds.	Pounds.	Pounds.	Pounds.	Pounds.
On silage ration.....	2,276.2	3.78	86.15	1,292.8	195.2	68.5	1,029.1
On dried corn-fodder ration ..	2,017.9	3.86	78.02	1,210.8	191.1	62.7	957.0
Grain from silage.....	258.3	-0.08	8.13				

“It will be observed that, although the total amount of dry matter furnished by each ration was practically identical, the yield of milk from the silage ration is 258.3 lbs., or 12.8 per cent, greater than that from the dried fodder ration for the same cows for a like period; and the yield of butter fat is 8.13 lbs. greater, or 10.4 per cent.”

About 6.8 per cent more dry matter was consumed on the silage rations than on the dried fodder rations. The animals gained about 200 lbs. on the silage. The results of the experiments are summarized as follows:

“(1) The cost of harvesting, storing, and preparing the dry matter contained in corn was greater in the form of silage than in the form of dried fodder.

“(2) The changes that occur in the composition of silage were not such as to decrease its feeding value in a greater degree than those which occur in the process of curing corn fodder; and the losses due to spoiling in the silo amounted to 4 per cent of the total amount stored.

“(3) For milk and butter production the feeding value of the dry matter of the silage was greater than that of the dried fodder corn. The yield of milk was 12.8 per cent greater and the yield of fat 10.4 per cent greater.”

On the basis of these experiments it is estimated that about \$10 per acre more would be realized for corn fodder when preserved and fed in the form of silage than as dried fodder.

**Further experiments in cream ripening—flavor, aroma, acid,** H. W. CONN (*Connecticut Storrs Sta. Rpt. 1896, pp. 17-13*).—As showing the variation in the number and character of the bacteria at different times a series of experiments with 8 cows are reported in which the milk of each cow was examined for bacteria at different intervals. There was found to be a great difference in the number of bacteria from different cows at the same time and also great variety in the bacterial flora at different times. No 2 of the samples from the first

testing underwent the same kind of fermentation; and when the milk was tested later there was a noticeable change in this respect. Mention is also made of the variations in the bacteria found at the same creamery at different times.

The main part of the article is devoted to the results of experiments with 68 species of bacteria. These were all distinctly dairy bacteria, some being collected directly from cream at creameries, others from milk, others from the dust which fell from the cow during milking, etc. All of the general types of milk bacteria were included in the list. The experiments were with pasteurized cream. In each series of experiments one lot of the cream was ripened with the bacteria in question and another lot was left without any starter. No technical descriptions are given of the different species, but brief statements are given regarding the origin of each species and its effect upon the cream and the butter. The results are classified and discussed at considerable length.

"The majority of the species tested may be regarded as indifferent in their effect upon the butter. About half of them, when used to ripen the cream, as will be seen in the experiments described below, produced butter that had neither flavor nor aroma nor acid, and the butter was practically indistinguishable from the control butter. These species are the largest in number and are present in the greatest variety around barns and dairies. . . .

"A considerable portion of the species found are positively favorable in their influence upon the butter. Of the 68 species tested, 20 produced butter that has been described in our notes as good flavored. . . .

"Of the 20 above mentioned, 9 were lactic organisms. On the other hand, 11 were among the class which would be described as alkaline species, by which it is meant that they either produced an alkaline reaction in the milk or produced no change in its reaction. They are at all events distinctly not acid forms. Seven among them liquefy gelatin and are, therefore, among what are called the putrefactive bacteria. . . .

"A smaller number of species produced injurious effects upon the butter; 18 species among the 68 tested have been described as producing butter that was bad, or poor, or strong flavored, or disagreeable; various adjectives being used to indicate the different effects. Sometimes the poor flavor was a putrefactive taste; in other cases it was a bitter taste; in others, again, a strong sour taste; while in still others the effect was of a peculiar indescribable character. In many of these 18 species the unpleasant flavor was very slight, and probably insufficient to materially injure the butter. . . .

"Of the 18 species described as producing injurious effects upon the flavor of the butter, 9 belonged to the acid-producing class, while 9 belonged to the class developing alkaline reaction.

"From these facts it appears to me a safe and perfectly legitimate inference that flavor is a matter entirely distinct from acid. It will be noticed that among the acid-producing species there are some that develop good flavor, while others develop a decidedly unpleasant flavor; and it will be noticed that among the species producing good flavors in the butter, while many of them are acid producers, a large number, 11 out of 20, are among those that develop no acid. . . .

"While, therefore, the lactic bacteria may be regarded as commonly producing the butter flavor in practical butter making, they do not do this simply because they produce acid, and we must recognize that other types of bacteria probably assist in producing the desired flavor. It is important to note in this connection that of the 30 species described as indifferent in their action, none were acid organisms.

“Perhaps the most interesting result has to do with the production of the butter aroma. The butter aroma, the character that affects the nose rather than the palate, appears to be, at least so far as the results of the experiments are concerned, entirely independent of the flavor. Moreover, it appears to be a more unusual thing for bacteria to produce a desirable aroma than a desirable flavor. The great majority of these species tested give rise to practically none, or at least to an extremely slight aroma. Thirty-nine produce no aroma at all, [and] the majority, again, are among the class which either develop an alkaline reaction in the cream or do not change its reaction at all. Seven of those producing no aroma are among the class that produce lactic acid. Among those that do produce an aroma of a decided character, 18 are described in my laboratory notes as producing an unpleasant or a bad aroma; 7 of these are among those that produce lactic acid. . . . Only 8 have been found as yet to produce an aroma which has been described in my notes as good; and in only 3 has the aroma been that which is looked for in first-class butter. In 2 or 3 cases the aroma produced was of an extremely fine character, and in these artificial tests almost identical with the aroma expected in the first-class butter from a creamery. It has been interesting to find that, of the 8 species which produce the aroma which has been described as good, none has been among the acid-producing organisms. The 8 either develop an alkaline reaction or have no special effect upon the reaction of milk. There were 3 which developed the most typical aroma of all the species studied. Two of these curdled milk by producing a rennet, both liquefying gelatin. The third did not curdle the milk. This result has been a surprise to me, inasmuch as I had supposed before the experiments began that the aroma was a matter very closely associated with the development of the lactic acid. . . .

“It has been found in these experiments thus far that none of the species tested combines all of the 3 characters—the power of producing flavor, acid, and aroma. Some develop flavor with the acid, others develop aroma with flavor, and others develop aroma without any special flavor. As yet no single species has been discovered that produces all simultaneously. This result is not, of course, surprising, for, recognizing that the ripening of cream must be an extremely complicated process, and produced by a large number of species of bacteria working together, it is a natural inference that the different qualities in the butter may be caused by different species of bacteria. It is by no means to be implied, however, that the 3 properties may not be combined in some species of bacteria.”

In conclusion, it is noted that some of the species of bacteria producing good flavor in the butter were quite widely distributed during the month of June. One species in particular which gave a good flavor and a strong acid was found during the months of May and June in each of the creameries from which cream was taken. This is suggested as a possible explanation of the generally high quality of butter made during these months.

**Bacillus acidi lactici and other acid organisms found in American dairies, W. E. ESTEN** (*Connecticut Storrs Sta. Rpt. 1896, pp. 44-52*).—This is the result of a study of the occurrence of these organisms in milk from different sections of the country. Samples of milk were collected within a wide extent of territory, including the New England States, New York, Pennsylvania, and Ohio. Fifty-three samples of milk were obtained from 30 different dairies. From these, 111 colonies were isolated, 34 of which were discarded as not producing acid or as being nearly anaerobic; and of the 77 remaining 47 appeared to be the same species—*Bacillus acidi lactici*.

The history of early work on this organism, technique of experiments and analysis of the principal organism, and the physiological and morphological characters of *Bacillus acidi lactici* as found in milk in the United States are discussed at considerable length.

As to the habitat of this organism, experiments were made with hay and hay dust and with milk direct from the cows. No organisms resembling *Bacillus acidi lactici* were propagated from hay or hay dust, but the experiments with milk direct from the cow "suggest the possibility that *Bacillus acidi lactici* comes from the cow in the milk duct, since its maximum temperature of growth is about that of the body temperature."

Three species of organisms were found which resembled *Bacillus acidi lactici* so closely that the author considers them varieties of that organism. The first differed from it by not growing at 35° C., and by rendering milk strongly acid without curdling it; the second was almost identical with the first, except that it rendered milk only slightly acid; while the third was like the second, but grew at 37.5° C. Many of the samples of milk yielded a nearly pure culture of *Bacillus acidi lactici*.

"It is necessary to repeat more fully the experiments in the territory covered and to obtain data from other places before a valuable scientific conclusion can be drawn. It is of course possible that the 47 organisms isolated are a collection of many species, but the evidence from the data obtained leaves no doubt in my mind that they are the same species.

"Milk from 30 widely separated localities in New York, Pennsylvania, Ohio, Maine, New Hampshire, Massachusetts, Rhode Island, and Connecticut yielded, with 2 exceptions, apparently the same organism. This fact throws the weight of evidence on the side of the belief that one organism universally exists in the territory studied, which produces the ordinary souring and curdling of milk. This organism seems to be identical in every particular with that of Günther and Thierfelder, who concluded that their organism was the same as Lister's *Bacterium lactis* and Hueppe's *Bacillus acidi lactici*."

**A new milk preservative**, A. W. STOKES (*Analyst*, 22 (1897), Dec., pp. 320, 321).—The "Rhodian purifier," which it was claimed would keep milk sweet for several days, in the warmest weather, was found to consist of potassium nitrate and water, there being 19 per cent of the nitrate. It had no merits as a preservative. Its presence in milk is detected when the milk solids are incinerated by deflagration, and the ash if taken up in dilute sulphate gives the nitrate reactions. In testing milk by the Gerber, Leffman-Beam, or Babcock processes a yellow color appears when the milk containing this preservative is mixed with strong sulphuric acid and minute bubbles of nitrous gas are given off.

**A new milk adulterant**, A. W. STOKES (*Analyst*, 22 (1897), Dec., pp. 321, 322).—A "secret nostrum for concealing the addition of water to milk" was found to contain 1.96 per cent of dextrin. It was claimed that 20 per cent of water could be added to milk without fear of detection, provided 4 oz. of the material was added per pint of milk. It was said to be used extensively in Australia. It could be detected by the small amount of unaltered starch it contained, which gave the iodine reaction.

**The dairy herd: Its formation and management**, H. E. ALVORD (*U. S. Dept. Agr., Farmers' Bul. 55, pp. 24*).—This is a reprint with revisions from the Yearbook of this Department for 1894 (E. S. R., 7, p. 523).

**The development of dairying in Southwestern France** (*Milch Ztg., 26 (1897), No. 51, pp. 811-813*).

**Comparative studies on the milk production of Swiss and native goats**, W. WINTROP (*Milch Ztg., 26 (1897), No. 50, pp. 795, 796*).—A record for 13 Swiss and 10 native goats, covering several months, showing the average yields at each of the 3 milkings daily.

**Does the direct transmission of fat of the food to the milk take place?** H. WINTERNITZ (*Deut. Med. Wchenschr., 23 (1897), p. 477; abs. in Chem. Ztg., 21 (1897), No. 73, Repert., p. 200*).—The author made experiments in feeding animals pork fat to which iodin had been added. Finding iodin in the milk fat, he concludes that a direct transmission of the fat of the food to the milk may take place.

**The sesame oil reaction in natural butter**, A. SCHEIBE (*Milch Ztg., 26 (1897), No. 47, pp. 745, 746*).—A cow was fed 2 kg. (4.4 lbs.) of sesame cake per day. At the end of a week the butter made from the milk gave a weak but distinct reaction for sesame oil, and this continued with further feeding. Although the reaction was not as strong as in butter to which margarin containing sesame oil had been added, the author thinks it invalidates the sesame oil reaction as a test for margarin.

**Experiments in milking at different times**, H. HUCHO (*Milch Ztg., 26 (1897), No. 44, pp. 695-697*).—An account of experiments in milking sheep and a goat once, twice, and three times daily.

**The infection of milk by microbes**, M. E. CASTEL (*Dairymen's Assoc. Prov. Quebec, Rpt. 1896, pp. 216-233, figs. 17*).—A lecture illustrated by magic-lantern slides. Incidentally the results of some experiments on the infection of milk from the foremilk, the cow and the milk, unclean vessels, and barn air are popularly described.

**Ripening cream with kephir**, B. MARTINY (*Milch Ztg., 26 (1897), No. 48, p. 766*).—The author reports a trial on a small scale of ripening cream with a culture of kephir in milk. The butter was pronounced of good flavor and kept well for the short time under observation. The buttermilk was much improved in flavor over ordinary buttermilk. The author urges experiment stations to continue the study.

**Preservation of milk by partial freezing** (*Milch Ztg., 26 (1897), No. 50, pp. 796, 797, figs. 2*).—This is very similar to an article recently noted (E. S. R., 9, p. 581) on the partial freezing of milk for transportation.

**Milk standard of St. Petersburg** (*Chem. Ztg., 21 (1897), No. 101, p. 1058*).—To determine a proper normal the municipal laboratory examined 2,830 samples of milk. On the basis of this work it concludes that good milk should not contain less than 4 per cent of fat and 13 per cent of solids; and that milk offered for sale in the city containing less than 3 per cent of fat and 12 per cent of solids will be held unsatisfactory. Milk intended for hospitals, schools, etc., must fulfill all the requirements as to purity, freshness, taste, odor, consistency, and nutritive value.

**Concerning the exactness of the determination of fat in cream by centrifugal testers**, H. SCHROTT-FIECHTL (*Milch Ztg., 26 (1897), No. 52, p. 830*).—Diluting the cream with water or skim milk of known composition was found unsatisfactory with different tests. The cream-testing bottle with the Babcock test gave results which compared as favorably with the gravimetric results as are obtained in the case of milk.

**Butter making on the farm**, C. P. GOODRICH (*U. S. Dept. Agr., Farmers' Bul. 57, pp. 15*).—This a popular bulletin on farm dairying, treating of the care and handling of milk, cream raising by deep setting and by separator, ripening cream, churning, mottles or "white specks" in butter, coloring butter, salting and working, and making butter to suit the customer.

With reference to the thoroughness of creaming, the author gives the results of tests of skim milk brought by farmers to farmers' institutes in the State of Wisconsin.

"For 2 years the writer preserved the report of these tests, and the average of all was 0.8 for the skim milk creamed by any gravity method. It varied from 0.25 per

cent to 1.6 per cent. This was in the winter, when there was no difficulty in having the milk cold enough. There is no doubt that in summer, during hot weather, the average loss is still greater. If the separating is done on the farm immediately after the milking, the skim milk from the separator seldom tests more than 0.1 per cent, and frequently less than that.

“From the result of these tests it seems impossible to escape the conclusion that the average loss, where the milk is set in pans, cans, and crocks, is  $\frac{3}{4}$  of a pound of butter more to each 100 lbs. of milk than where the separator is used. This means, with milk of average richness (3.5 per cent butter fat), a loss of about 20 per cent of the total product of butter. A herd of cows ought to average, per cow, 5,000 lbs. of milk per year, and would do so if made up of good animals and well managed; but even if they only average 3,000, the loss on one cow would be 22½ lbs. of butter and on 10 cows 225 lbs., which, at 20 cts. per lb., would be \$45 a year.”

**On butter aroma**, H. WEIGMANN (*Centbl. Bakt. u. Par., 2. Abt., 3 (1897), No. 19-20, pp. 497-504*).—This is a controversial article in which the author discusses the origin of the aroma of butter under normal conditions, and takes exception to the value of organisms isolated especially for their aroma-producing qualities, since such organisms easily lose their specific action under those conditions.

**Home-made fancy cheese**, G. E. W. (*Sci. Amer., 78 (1898), No. 4, p. 54*)—Popular directions for making Roquefort, Stilton, Gorgonzola, and Génomé or Gérardmer cheese.

**Notes on cheese making from sheep's milk in Transylvania**, P. THIELE (*Milch Ztg., 26 (1897), No. 46, pp. 727-729, fig. 1*).—Directions are given for making 3 kinds of cheese.

**On the Thistle milking machine**, SCHÜTT and AHRENS (*Milch Ztg., 26 (1897), No. 44, pp. 702, 703*).

**Wahlin's patent butter accumulator** (*Milch Ztg., 26 (1897), No. 51, pp. 813, 814, figs. 2*).—An illustrated description of this English butter extractor.

**The Radiator, a new separator and churn**, B. MARTINY (*Milch Ztg., 26 (1897), No. 50, pp. 791, 792*).

**Experiments with the Radiator**, B. MARTINY (*Milch Ztg., 26 (1897), No. 52, pp. 823, 824, figs. 2*).—A brief résumé of some experiments with this apparatus in France, Sweden, and Germany.

## AGRICULTURAL ENGINEERING.

**Windmills for irrigation**, E. C. MURPHY (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 8, pp. 19, pls. 8, figs. 30*).—This is a condensed report of results of experimental tests carried on during the summer of 1896 upon windmills located for the greater part in the vicinity of Garden, Kansas.

“The pumping power of windmills, or the useful work they do when raising water with reciprocating pumps of sizes from 4 to 10 in. diameter, is small—not greater than 0.65 of 1 horsepower for 12-foot mills, and much less than that claimed for them by some windmill makers. . . .

“Perhaps the most important result shown by these tests, and one that has not been clearly shown before, as far as the writer has seen, is the influence of load on mill, or a number of foot-pounds per stroke of pump on the power of a mill. . . . The tests show that for high velocities—20 or 30 miles—the power is very nearly proportional to the load on the mill. For 30 miles per hour, a brake load of 2 lbs. gave 0.54 horsepower; a 4-pound load, 1.09 horsepower; and a 6-pound load, 1.55 horsepower. . . .

“Another fact brought out by these tests, and which follows as a result of the previous ones, is that there should be some automatic device for increasing the load

on a mill as the wind velocity increases. When the velocity is low—say 6 miles per hour—the load should be small enough to enable the wind wheel to run at a rapid rate—the rate for maximum power—and then as the wind velocity increases the load should be increased so as not to allow the wheel to run at a higher speed. This is a very promising field for the inventor.

“If the load can not be automatically increased as the wind velocity increases, then the question arises, What is the proper or most economical load? This depends on the velocity of the wind each month at the given place. During the months of July and August there are a greater number of hours of low wind velocity than during any other 2 months of the year. The load should be light during these months for the greatest power. . . .

“The useful work that a windmill will do when working under a constant load at all velocities is small, the horsepower varying as the first power of the velocity. By some device for automatically increasing the load as the wind velocity increases, the power may be much increased at high velocities, and will then vary as the second power of the velocity. Even with this device for increasing power there is still a great difference between the power possessed by the wind and the power developed by the mill, and this difference increases as the velocity increases.”

**An experiment with a steam drill, C. H. PETTEE** (*New Hampshire Sta. Bul. 46, pp. 59-76, pls. 7*).—An account is given of the improvement of a street in the town of Durham commanding the approaches to the college. In carrying out this work it was necessary to reduce a hill 510 ft. in length to a uniform grade (1 in 20 and 1 in 22), to make several fills, and to remove the masses of rock which encroached upon the roadway and forced it to one side. For the latter purpose a portable steam drill capable of drilling 4 to 5 ft. per hour was used.

Tables give the cost of equipment, blasting rock, and handling material, from which it appears the cost of handling rock, including the work with the drill, was \$1.11 per cubic yard and was greater than that of the earth fill.

“There is need, however, of a large amount of rock work upon the average country road. The steam drill is absolutely essential for the economical handling of considerable rock masses, and is capable of doing exceedingly economical work, in portable form, for small amounts of work in a place.”

The comparative cost of moving different road materials and the question of a standard grade are briefly discussed.

**A practical study of road maintenance, C. H. PETTEE** (*New Hampshire Sta. Bul. 46, pp. 77-88*).—This is a report of a critical study of the work of the highway agents of the town of Durham during the year ending in March, 1897, and includes comments on the keeping of accounts and general management, road surfacing, road machines, highway laws, and public opinion on highway maintenance.

**Irrigation practice on the Great Plains, E. B. COWGILL** (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 5, pp. 39, pls. 12, figs. 8*).—This paper gives the experience of a practical farmer and irrigator with methods of utilizing the water resources of semi-arid areas, and is devoted to the following topics: Reservoirs for storm waters, reservoirs for pumped water, ditches, distributing water, methods of watering, cultivation, subirrigation, amount of water required, and winter irrigation.

**Irrigation in Connecticut**, C. S. PHELPS (*Connecticut Storrs Sta. Rpt. 1896*, pp. 216-245, figs. 2).—The main features of this article will be found in U. S. Dept. Agr., Office of Experiment Stations Bul. 36, pp. 9-26 (E. S. R., 9, p. 97).

**Seepage water of Northern Utah**, S. FORTIER (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 7*, pp. 50, pls. 3, figs. 13).—"The facts herein presented are based upon field work carried on mainly during the summer of 1896, and have special value in illustrating conditions which prevail to a greater or less degree throughout all irrigated lands, especially within inclosed valleys or on long, narrow drainage systems." Many of the data here reported are also given in Bulletin No. 50 of the Utah Station (E. S. R., 9, p. 427).

**Report of the engineer**, O. V. P. STOUT (*Nebraska State Bd Agr. Rpt. 1896*, pp. 95-104).—This is a report of measurements under the direction of the Nebraska State Board of Irrigation of the rate of discharge during the growing season of 1896 of the following Nebraska streams: Frenchman River at Palisade, Republican at Superior, North Platte at Camp Clarke, North Platte at North Platte, Platte at Columbus, Middle Loup at St. Paul, North Loup at St. Paul, Loup at Columbus, Elkhorn at Norfolk. Besides these regular observations, a table of measurements of discharge at other points than the gaging stations is given.

**Digest of the general and special road laws of Pennsylvania**, A. D. HARLAN (*Pennsylvania Dept. Agr. Bul. 18*, pp. 129).—This is a digest "of all of the General Laws of Pennsylvania, referring to roads, highways, and bridges, up to and including the session of 1895. Also an index to road, highway, and bridge laws as they affect municipal corporations, including cities of the first, second, third, fourth, and fifth classes, together with an index to all special county and township road laws."

**Cheap silos in Virginia**, D. O. NOURSE (*Virginia Sta. Bul. 70*, pp. 115-119).—A brief account is given of the successful use of cheap silos at the station, especially of a stave silo, the cost and details of construction of which are given. A table which shows the capacity of round silos of different sizes is added.

## STATISTICS—MISCELLANEOUS.

**Reports of executive committee, treasurer, and director of Connecticut Storrs Station, 1896** (*Connecticut Storrs Sta. Rpt. 1896*, pp. 3-16).—Includes lists of the trustees and officers of the station; report of the treasurer for the fiscal year ending June 30, 1896; a brief report by the executive committee on the general conduct of the station; and a report by the director, reviewing in detail the work of each department of the station for the year.

**Seventh Annual Report of North Dakota Station, 1896** (*North Dakota Sta. Rpt. 1896*, pp. 51).—This contains the organization list of the station; reports by the chemist, veterinarian, horticulturist, botanist, and agriculturist, and of the departments of dairying and domestic science, parts of which are noted elsewhere; and a financial statement for the fiscal year ending June 30, 1896.

**Ninth Annual Report of South Carolina Station, 1896** (*South Carolina Sta. Rpt. 1896*, pp. 32-48).—Brief reports are given by the director and heads of departments on the work of the year, parts of which appear elsewhere, and a financial statement for the fiscal year ending June 30, 1896.

**Annual Report of South Dakota Station, 1897** (*South Dakota Sta. Rpt. 1897*, pp. 5).—Brief remarks by the director on the publications and the general conduct of the station during the year with a review of the work accomplished in each of the departments, and a financial statement for the fiscal year ending June 30, 1897.

**Annual Report of Virginia Station, 1896** (*Virginia Sta. Rpt. 1896*, pp. 13).—Brief reports by the director and heads of departments on the work of the year, with list of bulletins published, and a financial statement for the fiscal year ending June 30, 1896. Some meteorological data included within these pages is noted elsewhere (see p. 731).

**Reports of director and treasurer of West Virginia Station, 1891** (*West Virginia Sta. Rpt. 1891, pp. 4-20*).—The texts of the Hatch Act of March 2, 1887, of the State act accepting appropriations from the United States Government for the establishment and maintenance of an agricultural experiment station, and of State legislation relative to commercial fertilizer inspection are given, together with remarks on the plan of the station organization and work, and a financial statement for the fiscal year ending June 30, 1891.

**Ontario agricultural statistics, 1896** (*Ontario Bureau Ind. Rpt. 1896, pp. 1-155*).—This gives the acreage and classification of the assessed farm lands of each of the counties of Ontario in 1895 and 1896; acreage under pasture for the 5 years ending 1896; acreage under crops for each of the years 1892 to 1896, and the average for the 15 years 1882 to 1896; yield in bushels of the different farm crops for 1895 and 1896 and the average yield for the 15 years ending with 1896; extracts from remarks of correspondents on crop and live stock conditions during 1896; data showing the acreage in gardens, vineyards, and orchards and the number of trees of bearing age, and the yield of apples in 1895 and 1896; statistics on the weather noted elsewhere (see p. 731); live stock, dairy, and apiary statistics, with the name and post-office address of the secretary of each cheese factory in the Province; value of farm property, live stock, and farm crops for each of the 15 years 1882 to 1896; and the rate of wages paid farm laborers by the year and by the month with and without board for each of the years 1892 to 1896 and the average for the 15 years ending with 1896.

There is an almost regular decrease in the value of farm lands for the past 14 years, the decrease in 1896 being \$15,470,202 over the preceding year, and \$97,324,745 over the year 1883; the total value of all farm property, including buildings, implements, and live stock has also decreased since 1883, being more than \$51,000,000 less than at that time. The rate of wages paid farm laborers in general shows a constant decline, each year's average being less than the previous  $\frac{1}{2}$  year and less than the average for the preceding 15 years.

**Farm statistics of Michigan, 1896-'97** (*Rpt. Sec. State Michigan, 1896-'97, pp. XLIX, 123*).—This gives the acreage and yield of farm and orchard crops, and the number and kinds of farm animals in the State in 1897, together with the number of sheep and the wool production of 1896.

**Agricultural improvements at the Meerut demonstration farm in 1896** (*Agr. Ledger (Agr. ser., No. 17), 1896, No. 18, pp. 5*).

**Report of the superintendent of farmers' institutes of the Province of Ontario 1896-'97**, F. W. HODSON (*pp. XL, App. pp. 240*).—A review of the work of the year with lists of officers, meetings, speakers, subjects, etc.; data showing membership of local farmers' institutes, meetings held, attendance, cash receipts and expenditures, etc.; and an appendix containing reprints of 93 selected papers read at different institutes during the season. The summarized statement of the author shows that 3,277 addresses on agricultural topics were delivered during the year, and that 659 meetings were held, with a total attendance of 125,127 persons.

**Dates and places of farmers' institutes in Pennsylvania for the season of 1897-'98** (*Pennsylvania Dept. Agr. Bul. 25, pp. 8*).

**Experiment station work—I** (*U. S. Dept. Agr. Farmers' Bul. 56, pp. 31*).—This is the first of a series of brief popular bulletins based upon the work of the agricultural experiment stations, the object of which is to show some features of the progress of agricultural investigation on its practical side. The following topics are briefly treated: Good *vs.* poor cows, corn *vs.* wheat, effect of rations richer and poorer in protein, forage crops for pigs, Robertson silage mixture, alfalfa, effect of fertilizers on the proportion of grain to straw or stover, comparative fertilizing value of different phosphates, the harmful effects on soils of the continued use of muriate of potash, recent progress in the study of irrigation, potato scab, and barnyard manure.

## NOTES.

---

IOWA STATION.—The experiments conducted last year to determine the cost of production and value of the product from the various breeds of hogs, including the English bacon breeds, together with a final test on the foreign market and a chemical analysis of representatives of each by the United States Department of Agriculture, are being repeated. The range lamb feeding experiment reported last year in Bulletin 35 is being repeated this winter; and a carload of range-bred calves, including 6 each of high-grade Herefords, Angus, and Shorthorns, are under investigation to determine the economy of feeding that class of stock in the corn-belt agricultural States. The dairy herd of about 40 cows, containing good representatives of 4 pure breeds, has been under careful study and investigation with reference to determining the cost of production from the several types and breeds during the past year, and exceedingly interesting and valuable results have been obtained. This work will be continued indefinitely and a summary of results published at the end of the second or third year, supplemented by other reports later.

MISSOURI COLLEGE AND STATION.—The special committee appointed by the State Board of Agriculture to examine the Missouri Agricultural College and Experiment Station has issued a very favorable report, showing an excellent condition of all work at Columbia.

RHODE ISLAND STATION.—A. A. Brigham, professor of agriculture in the college, has been made director of the station.

TEXAS STATION.—The station has resumed the publication of press notes, discontinued for two years. In revising its mailing list the station has classified its publications under the 3 heads, "General farm crops," "Fruits and vegetables," and "Stock husbandry," and has requested that those on the mailing list indicate which class or classes of bulletins they are especially interested in. The result is quite satisfactory and will effect a considerable saving in the cost of bulletins. Many write that they do not care for more than one or two classes of reports. About 1 in 4 want them all.

PERSONAL MENTION.—Dr. G. Kranse, of Halle, has been tendered the professorship of botany at Würzburg, held by the lately deceased Julius Sachs.

In consequence of the gift by F. Kempe of 150,000 crowns there has been established a professorship of plant biology in the University of Upsala, and Dr. Lundstrum has been chosen as the first occupant of the new professorship.

Dr. Manly Miles died February 16, 1898, at Lansing, Michigan. Dr. Miles was associated with agricultural education and experimentation for many years, and was the author of several books on agricultural topics, notably one on stock breeding.

Charles Ernest Cornevin, professor of zootechny and general hygiene in the National Veterinary School of Lyons, France, and in the School of Practical Agriculture of the Rhone, died November 24, 1897, at the age of 51 years. He was the author of an excellent treatise on zootechny and has made extended studies on poisonous feeding stuffs and on the use of the industrial by-products in the feeding of animals, including, among others, experiments with *Cytisus*, potatoes, and castor-bean and cotton-seed cakes. The results of these studies are embodied in two books, entitled *Les plantes vénéneuses considérées au point de vue de l'empoisonnement des animaux de la ferme* and *Des résidus industriels dans l'alimentation du bétail*. He also made valuable contributions to the knowledge of animal diseases. He investigated hog cholera and gangrenous septicæmia, and in connection with Arloing and Thomas showed the distinction between symptomatic charbon of cattle and charbonous fever, proposing a successful method of vaccination against the former.

Committee of the Association of Official Agricultural Chemists.

## CONTENTS of Vol. IX, No. 9.

Editorial notes:	Page.
The new building of the College of Agriculture of the Ohio State University .....	801
Government investigations in Alaska .....	803
Recent work in agricultural science .....	805
Notes .....	900

### SUBJECT LIST OF ABSTRACTS.

#### CHEMISTRY.

Report of the chemical control station at Christiania, Norway, 1896, F. H. Werenskiold .....	805
Spontaneous combustion of hay, G. C. Watson .....	807
The soluble starches, W. Syniewski .....	806
Chemical department, R. De Roode .....	807
Changes in and additions to methods of analysis adopted at the 13th and 14th annual meetings of the Association of Official Agricultural Chemists, H. W. Wiley .....	808
Miscellaneous analyses, J. L. Hills, B. O. White, and C. H. Jones .....	808

#### BOTANY.

Contributions to the life history of <i>Amphicarpa monoica</i> , Adeline F. Schively. ....	809
A chemico-physiological study of <i>Spirogyra nitida</i> , Mary E. Pennington .....	809
On the structure and pollination of the flowers of <i>Eupatorium</i> spp., Laura B. Cross .....	809
The correlation of growth under the influence of injuries, C. O. Townsend....	810
Periodicity of root pressure, M. B. Thomas .....	810

	Page.
The amount of nitrogen conveyed by red clover to different kinds of soil, N. Passerini .....	811
Nitrogen nutrition of the Leguminosæ, K. von Rozdejezer.....	811
FERMENTATION—BACTERIOLOGY.	
The bacteriological flora of the air in stables, A. W. Bitting and C. E. Davis ..	813
Studies on nitrification, H. Weissenberg.....	813
METEOROLOGY.	
Monthly Weather Review, Vol. XXV, Nos. 10-12.....	814
Meteorology of 1896, W. S. Sweetser.....	815
Meteorological report for 1895, J. C. Rane .....	816
Meteorological observations, L. H. Merrill.....	816
Floods of the Mississippi River, P. Morrill.....	816
Monthly reports of the River and Flood Service for September, October, November, and December, 1897, P. Morrill.....	817
Forest and rainfall, H. A. Hazen .....	817
The highest kite ascensions at Blue Hill, S. P. Fergusson .....	816
Instructions to operators on the United States seacoast telegraph lines, J. H. Robinson .....	817
A winter barograph curve from the South Pacific Ocean, R. De C. Ward.....	817
An improved sunshine recorder, D. T. Maring.....	817
The probable state of the sky along the path of total eclipse of the sun May 28, 1900, F. H. Bigelow.....	817
Instructions governing the corn, wheat, cotton, sugar, and rice region service, J. Berry .....	817
WATER—SOILS.	
Analyses of drinking water, J. L. Hills, B. O. White, and C. H. Jones.....	821
Water used for irrigation on the station farm, J. A. Widtsoe .....	821
The rocks and soils of Grenada and Carriacou, J. B. Harrison .....	817
Soil temperatures at different depths, P. Sollied.....	818
Soil temperatures, W. S. Sweetser.....	819
Influence of the humidity of the soil on the development of flax, D. N. Pryanishnikov and R. G. Trube .....	819
On the assimilation of the nitrogen of some organic compounds in sterilized media, D. N. Pryanishnikov and A. N. Lyebedyev .....	820
On the oxidation of the ammonia produced by soil organisms, E. Demoussy ..	820
The use of vegetation experiments in soil analysis, H. Wilfarth.....	820
The improvement of muck soils, F. T. Shutt.....	821
On the relative influence of phosphatic fertilizer on various soils and on the solubility of the phosphoric acid contained in these soils in a 2 per cent citric-acid solution, D. N. Pryanishnikov and B. A. Skalov.....	821
FERTILIZERS.	
Preservation of barnyard manure, F. T. Shutt.....	822
Utah guano, J. D. Widtsoe.....	825
Analyses of miscellaneous fertilizers, J. L. Hills, B. O. White, and C. H. Jones.	825
Is there a constant relation between the solubility of phosphatic slag in ammonium citrate and the weight of the crop produced? A. Petermann and J. Graftiau.....	822
General fertilizer experiments, E. H. Hess.....	823
Recent researches on reverted phosphoric acid, J. Stoklasa .....	823
Are the compounds of phosphorus and sulphur found in moors and which are insoluble in strong acids also present in moor plants? M. Schmoeger.....	824

## FIELD CROPS.

	Page.
Report of the agriculturist, D. D. Johnson .....	832
Results obtained in 1897 from trial plats of grain, fodder corn, and roots, W. Saunders .....	826
Experiments with corn, J. F. Duggar .....	828
Meadows and pasture formation and cultivation in the Middle-Eastern States, J. G. Smith .....	828
Farm crops at the experimental farm at Brandon, Manitoba, S. A. Bedford ..	829
Field experiments with small grain and root crops, W. Saunders .....	830
The profitable amount of seed per acre for corn, J. M. Bartlett .....	830
The Irish potato, R. H. Price .....	830
The composition of potatoes, J. A. Widtsoe .....	831
The ripening of sugar beets, J. A. Widtsoe .....	831
Sugar beet experiments in Arizona, R. H. Forbes .....	833
Variety tests—wheat, oats, and potatoes, E. H. Hess .....	832

## HORTICULTURE.

Notes on winter gardening, W. M. Munson .....	840
Reference list of publications relating to edible and poisonous mushrooms, Josephine A. Clark .....	840
Orchard notes, W. M. Munson .....	834
The cherry in Delaware, G. H. Powell .....	834
Winter protection of the peach, J. C. Whitten .....	835
The cultivation and management of the peach, J. C. Whitten .....	837
Problems in plum pollination, F. A. Waugh .....	837
Classification of plums, F. A. Waugh .....	839
Report on fruits at Huntington, E. A. Bennett .....	841
The preservation of fruits by vapor of alcohol, F. A. Waugh .....	839
A new grafting machine, F. A. Waugh .....	841
The Italian, or orchid-flowering, cannas, F. A. Waugh .....	842

## FORESTRY.

The timber pines of the southern United States, C. Mohr .....	842
Forest trees, A. Mackay .....	843
Care of woodlands, W. H. Buckhout .....	844

## SEEDS—WEEDS.

Preliminary report on the artificial use of enzymes in germination, F. A. Waugh ..	844
Weeds and seeds, F. L. Harvey .....	845
Notes on plants, F. L. Harvey .....	846

## DISEASES OF PLANTS.

Report of the botanist, L. R. Jones .....	846
The cause of a brown rot in cruciferous plants, E. F. Smith .....	847
The black rot of the cabbage, E. F. Smith .....	849
A bacterial disease of celery, U. Brizi .....	850
The core rot of apples and pears, J. Craig .....	850
A dry rot of apples, J. Craig .....	850
Apple and pear blight, J. Craig .....	851
Diseases of the Irish potato, R. H. Price .....	851
Spraying, A. B. Cordley .....	852
Spraying, J. Craig .....	851

## ENTOMOLOGY.

Some little-known insects affecting stored vegetable products, F. H. Chittenden ..	852
Report of the entomologist and botanist, J. Fletcher .....	855

	Page.
Report of the entomologist, A. D. Hopkins .....	857
Annual report of the entomologist, A. D. Hopkins .....	858
Notes on the insects of the year, F. L. Harvey .....	858
The army worm, B. H. Warren .....	858
The red spider, G. H. Perkins .....	859
A new garden Smynthurid ( <i>Smynthurus albamaculata</i> ), F. L. Harvey.....	860
The San José scale in Missouri, J. M. Stedman .....	862
A report on the occurrence of the cabbage root maggot, F. A. Waugh.....	862
A bacillus pathogenic upon the phylloxera and certain acarids, L. Dubois....	860

## FOODS—ANIMAL PRODUCTION.

Report of preliminary investigations on the metabolism of nitrogen and carbon in the human organism, W. O. Atwater, C. D. Woods, and F. G. Benedict...	863
The chemistry of the corn plant, F. T. Shutt.....	865
Analyses of fodders and feeding stuffs.....	866
Composition of Utah feeding stuffs, J. A. Widtsoe .....	872
Dried brewers' grains, H. P. Armsby .....	873
Miscellaneous fodder crops, J. L. Hills .....	873
Sunflowers and English horse beans as silage crops, J. M. Bartlett .....	866
The feeding value of broken hop vines, F. T. Shutt .....	867
Laeteo vituline (calf meal), F. T. Shutt.....	867
Relative digestibility of cheat and clover, G. W. Shaw and H. T. French.....	867
The composition of package tea, J. A. Widtsoe .....	868
The curing of meats .....	873
Dietary studies at the Maine State College .....	873
The computation of rations for farm animals, H. P. Armsby.....	873
Feeding steers, 1895-'96, W. Saunders .....	868
Feeding steers, S. A. Bedford.....	869
Experiments with cattle, A. Mackay.....	969
Notes on the cattle show of the Smithfield Club, G. Rogers.....	869
Pig feeding, J. L. Hills.....	870
Experiments in the fattening of swine, W. Saunders.....	871
The value of dairy by-products in pig feeding, F. B. Linfield.....	871
Experiments with swine, S. A. Bedford.....	872
Ducks and geese, G. E. Howard .....	874

## DAIRY FARMING—DAIRYING.

Dairying in Oregon, H. T. French, G. W. Shaw, and F. L. Kent.....	886
The effect of various preparations of molasses on milk secretion, Ramm.....	874
Studies of methods of experimental feeding trials, J. L. Hills.....	877
Some observations on the relation between body conformation and production in cows, E. A. Bogdanow.....	879
Experiments on the effect of different grain and concentrated feeds on the milk production of cows, Ramm.....	879
Feeding experiments with milch cows, J. M. Bartlett .....	881
The food requirements and production of different breeds of cows, R. Gripen- berg.....	882
Feeding trials with silage and potatoes, J. L. Hills.....	883
Record of the station herd for 1895-'96, J. L. Hills.....	883
Care of milk on the farm, R. A. Pearson.....	886
A calculation of the total solids of milk, M. E. McDonnell.....	888
The effect of food upon the quality of butter, J. L. Hills.....	884
Report of the dairy investigator, F. B. Linfield .....	881
Preliminary investigations concerning the number and nature of bacteria in freshly drawn milk, V. A. Moore.....	884

	Page
The double-necked Babcock bottle for testing skim milk and buttermilk, M. E. McDonnell.....	885
Creameries or butter factories; advantages, location, organization, and equipment, H. E. Alvord.....	886
Test of separators, J. M. Bartlett.....	888
Tests of dairy apparatus, J. L. Hills.....	888
Composition of full-cream cheese, W. Frear.....	886
Gonda cheese, H. Hayward.....	888
The constitution of milk with special reference to cheese production, S. M. Babcock.....	888

## VETERINARY SCIENCE AND PRACTICE.

Investigations of diseases of domestic animals, T. Smith.....	888
Contagious diseases of animals in Great Britain, D. E. Salmon.....	892
A report on rabies in Washington, D. C., V. A. Moore and P. A. Fish.....	893
Texas fever in Australia, D. E. Salmon.....	893
Texas fever in Kansas.....	893
Infectious leukæmia in fowls—a bacterial disease frequently mistaken for fowl cholera, V. A. Moore.....	890
Leeches, P. A. Fish.....	890
An outbreak of a nonspecific disease among swine, V. A. Moore.....	891
Effects of tuberculin on tuberculous cows, F. L. Russell.....	891
Tuberculosis in the herd of dairy cattle at Aas Agricultural College, Norway, H. Isaachsen.....	891
The detection of tuberculosis in cattle, C. Curtice.....	893
Tuberculosis in swine, the nature of the disease, with a report of three cases, V. A. Moore.....	893

# EXPERIMENT STATION RECORD.

VOL. IX.

No. 9.

The completion during the current college year of a large and well-arranged building for the special use of the College of Agriculture of the Ohio State University is a notable event indicating the progress of higher education in agriculture in this country. Nothing in our educational history in recent years is more striking than the rapid increase in resources and students of the colleges and universities deriving their support mainly or entirely from the State and national treasuries. And it is very encouraging to the friends of agricultural education to observe that the facilities for technical training in agriculture are being increased in many of these institutions in a measure commensurate with the importance of the interests involved in such training. The employment of better trained teachers, the division of instruction in the complex subjects embraced in the science and practice of agriculture along the lines of well-defined specialties, the provision of adequate buildings and equipment, and the organization of courses of instruction to meet the needs of different classes of students mark the development of education in agriculture in ways which advancing pedagogical science has shown to be essential to success in modern educational systems. Already experience has shown that the proper organization and equipment of courses in agriculture on a broad and dignified plan which puts them on an equality with the other courses offered in a university is the surest way to attract and hold students and to enable the institution to exert its rightful influence in promoting the progress of agriculture in the region to which it especially ministers. The success of the Ohio State University in its agricultural work within the past few years has been marked, and the erection of the new building is taken as a convincing proof that the university will continue to strengthen and develop its work in this direction. Both instructors and students will naturally labor with renewed earnestness and enthusiasm in an environment which assures them that agriculture is recognized as of equal importance with other subjects in the estimation of the university authorities. We have

deemed this event of sufficient interest and importance to warrant us in giving here a brief description of the building, accompanied by some illustrations.

The building has been named Townshend Hall, after the late Dr. N. S. Townshend, "as a memorial of his public services and his work in advancing the cause of agricultural education." The exterior appearance of the building is shown in the accompanying illustration (fig. 7). It is 260 feet in length, and varies in width from 64 to 78 feet. It is of slow-burning construction and cost about \$70,000. It contains a basement and two main floors. Plans of the basement and first floor are shown (fig. 8).

The basement, which is 15 feet high, is entirely above ground on the rear of the building, and is amply lighted from all sides. At one

FIG. 7.—Townshend Hall, Ohio State University.

end is located the dairy department, with rooms for testing and pasteurizing milk and for butter and cheese making (fig. 9). An adjoining building, 16 by 30 feet, contains the boiler and engine for the use of this department. At the opposite end of the basement are accommodations for live stock, while lecturing upon or judging them. Adjacent to, but detached from, the soil storage room is a glass house, 30 by 40 feet, for the experimental study of soils and farm crops.

The first floor contains the offices, class rooms, laboratories, reading room, library, and museum of the department of agriculture. The museum will contain not merely specimens of farm products and samples of agricultural implements, but an attempt will be made to show the development of both Ohio and American agriculture and the industries intimately connected with it.

The second floor contains the office, library, laboratories, and class room of the department of agricultural chemistry. The main laboratory, located over the agricultural museum, is 65 by 75 feet, and will accommodate 100 students at a time. The lecture room, at the opposite end, will seat 160 persons. Adjacent to this is a suite of rooms for the department of veterinary medicine. An assembly hall for the Townsend Society, located in the center of the front over the entrance hall, will seat about 200 persons. Connected with this hall is an office for the editors of *The Agricultural Student*.

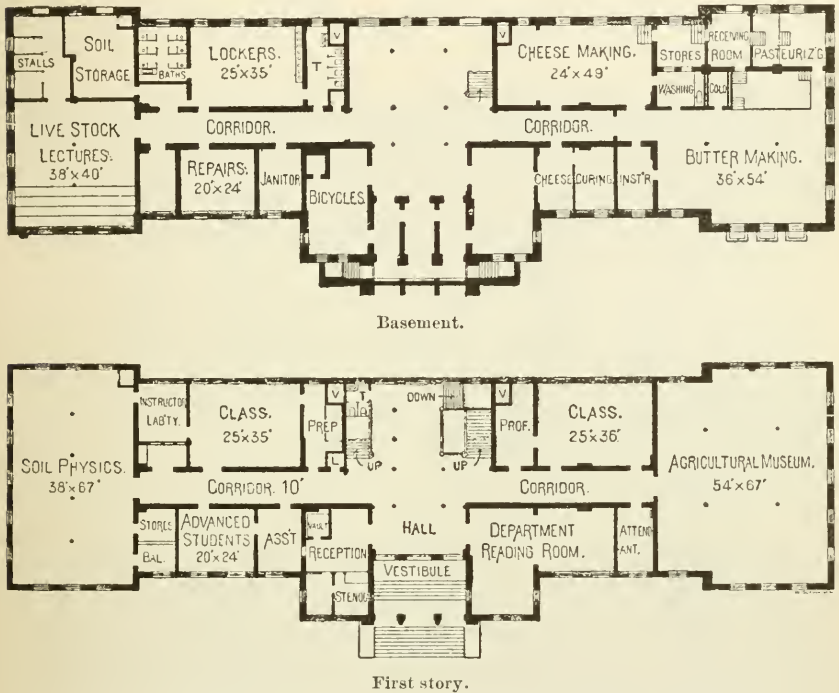

FIG. 8.—Townshend Hall, Ohio State University. Plan of basement and first story.

As the result of the report on the agricultural capabilities of Alaska, made by the agents of this Office at the close of last year, Congress has continued and increased the appropriation for investigations in Alaska with reference to the establishment of agricultural experiment stations there. Prof. C. C. Georgeson, formerly professor of agriculture in the Kansas Agricultural College, has been assigned to this Office as special agent in charge of the Alaska investigations. He will make his headquarters at Sitka, and will institute experiments with cereals, vegetables, and other crops at a number of places in that vicinity. He will also visit Kadiak Island, Cook Inlet, and other points north of Sitka with reference to the selection of land for experimental purposes and the institution of experiments with the cooperation of residents of

Alaska interested in the development of its agriculture. Questions relating to the temperature, moisture, and drainage of the soil, the curing and storage of forage plants, and the shelter and care of animals will receive early attention.

The Weather Bureau of this Department will also establish a special climatological service in Alaska the present season. A meteorological station will be located at Sitka and instruments will be furnished to voluntary observers in different parts of Alaska. In this way observations will be regularly made, which it is hoped will be of much service in the solution of agricultural problems, as well as of great importance to other interests in Alaska.

FIG. 9.—Townshend Hall, Ohio State University. Butter-making room.

The Geological Survey of the Department of the Interior has sent out parties to examine and map portions of Alaska hitherto almost or entirely unexplored. One party will survey the region adjacent to the 141st meridian, while others will explore the drainage basins of the White and Tanana rivers, the Kuskokwim River, and the Sushitna River. The several parties are expected to rendezvous at St. Michaels in September. In addition to these parties the War Department will send an expedition to explore the Copper River region. Two geologists will accompany this expedition.

## RECENT WORK IN AGRICULTURAL SCIENCE.

### CHEMISTRY.

**Report of the chemical control station at Christiania, Norway, 1896,** F. H. WERENSKIOLD (*Aarsber. Offent. Foranst. Landbr. Fremme, 1896, pp. 117-169*).—Of the more important data given in the report, mention is here made of the following:

*Alkaloids in cotton-seed meal.*—The author, in following the scheme of analysis outlined by Dragendorff, separated the chlorin compounds of 3 alkaloids, (1) by shaking the acid extract with chloroform, (2) by shaking the alkaline extract with chloroform, and (3) by digesting with chloroform the extract evaporated on pumice stone.

The compound separated by the second method proved to be cholin that by the third, betain; and that by the first, a new, perhaps unknown, alkaloid, at any rate one hitherto not identified in cotton-seed meal. The 3 alkaloids gave the same reactions with iodine-potassium iodide, phosphomolybdic acid, phosphotungstic acid, picric acid, tannin, corrosive sublimate, potassium-bismuth iodide, potassium-cadmium iodide, and potassium-mercury iodide. But they gave quite different reactions with gold chloride and platinum chloride. Platinum chloride dissolved in water gave no precipitate with 1 and 2, but a yellow precipitate with 3; platinum chloride dissolved in alcohol gave no precipitate with 1 and 2, but a yellow crystalline precipitate with 3. Gold chloride dissolved in water gave no precipitate in case of 1 and 2, but a yellow crystalline and difficultly soluble precipitate with 3. No. 1 crystallized by slow evaporation partly in octahedra or similar crystals, partly in feathery aggregates. The author proposes the name of gossypein for this alkaloid.

*Macroscopic impurities in milk.*—The author examined 64 samples of whole milk, skim milk, and cream for macroscopic impurities, and obtained the following average results:

*Impurities in milk and cream.*

	Number of samples.	Macroscopic impurities.	
		Average.	Range.
		<i>Mg. per liter.</i>	<i>Mg. per liter.</i>
Whole milk .....	36	2.6	0.1-4.1
Gravity skim milk .....	12	2.1	0-4.2
Centrifugal skim milk .....	3	.3	0-0.9
Cream .....	3	1.5	.8-2.0

The impurities were largely particles of litter and fodder, although particles of dung and fibers of straining cloths, etc., were found in nearly all samples. Woolen and colored cotton fibers from the clothes of attendants were found in nearly half the samples. For the sake of comparison, some other food articles were examined in the same manner, with results as follows: Granulated sugar, 65.3 mg. impurities per kilogram; "tea sugar" (fine granulated), 242.5 mg.; kitchen salt, 366 mg.

*Composition of Norwegian root crops.*—The investigation of Norwegian root crops, begun in 1893, was continued, and 67 samples of different kinds of roots analyzed. The average results of the analyses are shown below:

*Composition and yield of Norwegian root crops.*

	Water.	Protein.	Fat.	Crude fiber.	Sugar.	Ash.	Other sub-stances.	Yield per acre.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Bu.</i>
Carrots, (14 samples):								
Average .....	88.24	.97	.23	1.06	5.52	.80	3.29	517.5
Range .....	85.41-91.08	.67-1.52	.14-.37	86-1.35	3.69-6.30	.56-1.25	2.47-4.57	.....
Kohl-rabi (12 samples):								
Average .....	89.08	1.23	.23	1.22	5.71	.60	2.00	701.5
Range .....	86.58-90.87	.75-1.82	.16-.39	.92-1.62	4.88-7.18	.41-.82	.68-2.97	.....
Turnips, yellow flesh (22 samples):								
Average .....	91.12	.81	.20	1.08	5.10	.74	1.81	1,058.0
Range .....	89.07-92.85	.69-1.88	.10-.30	.82-1.61	2.52-6.24	.52-.95	1.16-2.71	.....
Turnips, white flesh (9 samples):								
Average .....	92.80	.88	.17	.98	3.34	.63	1.08	1,150.0
Range .....	91.67-93.71	.66-1.08	.11-.26	.73-1.20	2.81-4.12	.48-.89	.77-1.85	.....
Fodder beets (10 samples):								
Average .....	85.70	1.23	.17	.90	8.68	.99	2.37	1,265.0
Range .....	81.64-89.73	.91-1.72	.07-.53	.74-1.08	6.95-11.28	.77-1.14	.44-4.39	.....

—F. W. WOLL.

**The soluble starches,** W. SYNIEWSKI (*Ber. Deut. Chem. Gesell.*, 30 (1897), No. 16, pp. 2115-2118).—The author suggests a new method for the determination of soluble starches. Fifty grams of commercial sodium peroxid is dissolved in 500 gm. of cold water and mixed with 50 gm. of potato starch in 500 gm. of water. The jelly-like mass, which is filled with gas bubbles, is placed in cold water and shaken from time to time. After an hour the mass becomes completely fluid, the vigorous evolution of gas which has kept up meanwhile forming a scum on the surface of the liquid. A quantity of 95 per cent alcohol is then added to the solution, which causes the formation of a tenacious, sticky precipitate. The excess of solution is drawn off and the precipitate dissolved in cold water, the solution cooled, and acetic acid added drop by drop until neutral. If too much alcohol has not been used, hydrochloric acid may be used instead of acetic acid. The precipitate is again dissolved in water and acidified on cooling. After repeated precipitation in this manner a solution is finally obtained with scarcely a trace of ash. The water solution of this final product

is allowed to stand for some time, when a small amount of a flocculent yellow precipitate appears and the supernatant liquid becomes perfectly clear. From this solution the starch is precipitated by 95 per cent alcohol, rubbed up with alcohol, collected on a filter, washed with water-free ether, and finally dried in a heated vacuum. In this way a snow-white amorphous body without odor or taste was obtained, of the approximate formula,  $3C_6H_{10}O_5 \cdot H_2O$ .

This substance is easily soluble in cold water. It was impossible to keep a solution stronger than 12.5 per cent at ordinary temperature. In warm water it appeared to dissolve in any proportion. It gave a clear blue color with iodine, and was not changed by prolonged heating. It did not reduce Fehling's solution. It rotated the polarized light to the right, the specific rotation varying with the concentration.—J. P. STREET.

**Chemical department, R. DE ROODE** (*West Virginia Sta. Rpt. 1892, pp. 18-35*).—The work of the year in this department of the station is briefly summarized, and an account is given of a comparison of the author's method<sup>1</sup> for determining phosphoric acid and nitrogen in the same sample with the official methods on a large number of fertilizing materials.

"The results thus far seem to indicate very clearly that very accurate results may be obtained by determining the total phosphoric acid in a portion of the same solution in which the nitrogen is to be estimated; and that this is the case whether the plain Kjeldahl or the Gunning modification is used; or in case nitrates are present, whether zinc dust, zinc sulphid, or hyposulphite of soda is used. . . .

"As to the question of the use of permanganate of potassium, [in the author's opinion the results obtained] show beyond any doubt that its use is entirely without effect upon the percentage of the nitrogen obtained, even though used very liberally. However, if it should still be deemed necessary by some chemists, its use may be continued, its bad effects upon the determination of the phosphoric acid in the same solution being destroyed by the addition of a solution of oxalic acid in quantities just sufficient to accomplish the purpose, before diluting up to the mark or by other means."

The Burney method of solution (in sulphuric acid with the addition of potassium nitrate) in the determination of phosphoric acid gave fully as accurate results as solution in nitric and hydrochloric acids.

The author describes the following laboratory apparatus: Kjeldahl distillation flask covered with asbestos, siphon wash bottle, filtering tubes to be used in place of Gooch crucibles for potash determinations, and a pipette for use in the author's application of the Kjeldahl method to the determination of phosphoric acid and nitrogen, which is so graduated that the necessity for correction or calculation is obviated should the strength of the ammonia solution not be exactly 1.4 gm. of nitrogen per liter.

**Spontaneous combustion of hay, G. C. WATSON** (*Pennsylvania Sta. Rpt. 1896, pp. 55, 56*).—The author reports in detail an apparent case of spontaneous combustion of hay in one of the college barns.

<sup>1</sup> West Virginia Sta. Rpt. 1891, p. 21 (E. S. R., 9, p. 721).

The action of formic aldehyde on albumen, gelatin, and peptone, and its use in the analysis of foods and condiments, H. SERTZ (*Inaug. Diss., Erlangen; abs. in Hyg. Rundschau*, 7 (1897), No. 22, p. 1135).

On the effect of heating protein with water under pressure, E. SALKOWSKI (*Ztschr. Biol.*, 34 (1897), pp. 190-295).

Investigations on protein: I. Iodated egg albumen, F. HOFMEISTER (*Ztschr. Physiol. Chem.*, 24, No. 1-2, pp. 159-172).

Contributions to the chemistry of protein precipitation, H. SCHJERNING (*Ztschr. Analyt. Chem.*, 36 (1897), No. 10-11, pp. 643-663).

Contribution to the subject of the cleavage of casein by hydrochloric acid, T. PAUZER (*Ztschr. Physiol. Chem.*, 24, No. 1-2, pp. 138-141).

A contribution to the biological history of phosphates, L. JOLLY (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 15, pp. 538, 539).—Repeated maceration of sheep flesh in acetic and dilute nitric acids failed to remove all phosphoric acid, the treated flesh showing a decided yellow coloration on treatment with molybdic solution. The author therefore concludes that part of the phosphorus is in fixed combination.

The detection of gelatin in cream, A. W. STOKES (*Analyst*, 22 (1897), Dec., p. 320).—The suspected cream is mixed with an equal volume of a dilute solution of mercury in nitric acid and the whole vigorously shaken. The mixture is allowed to stand 5 minutes and then filtered. To the filtrate an aqueous solution of picric acid is added. If gelatin be present a yellow precipitate is immediately produced. The test is a delicate one and may be quickly applied.—L. H. MERRILL.

The estimation of boric acid in meat preparations, G. POPP and C. FRESENIUS (*Ztschr. Öffentl. Chem.*, 3 (1897), p. 188; *abs. in Vrtljschr. Chem. Nahr. u. Genussmitl.*, 12, No. 2, pp. 156, 157).

Determination of lactic acid, ULZER and SEIDEL (*Rev. Internat. Falsif.*, 1897, No. 5; *abs. in Milch Ztg.*, 26 (1897), No. 47, p. 749).

Description of the principal methods for determining heat of combustion, W. LONGUINE (*Beschreibung der Hauptmethoden welche bei der Bestimmung der Brennungswärme üblich sind.* Berlin: R. Friedlander & Co., 1898, pp. 112, pls. 4, figs. 21).

Changes in and additions to methods of analysis adopted at the 13th and 14th annual meetings of the Association of Official Agricultural Chemists, H. W. WILEY (*U. S. Dept. Agr., Division of Chemistry Circ. 4*, pp. 10).—These changes have been noted in the account of the proceedings of this convention already published in the Record (E. S. R., 8, p. 272; 9, p. 404).

Investigations on the quantitative estimation of grape sugar, E. PFLÜGER (*Arch. Physiol. [Pflüger]*, 69, No. 9-10, pp. 399-471, fig. 1).

The extraction of fluids, A. WROBLEWSKI (*Ztschr. Analyt. Chem.*, 36 (1897), No. 10-11, pp. 671-674, figs. 2).—The author describes an apparatus designed for the exhaustive extraction of fluids, in which the vapors of the ether or other solvent employed are forced through the fluid to be extracted. The consequent warming of the fluid, together with the agitation effected by the passage of the vapors, greatly facilitates the extraction.—L. H. MERRILL.

Miscellaneous analyses, J. L. HILLS, B. O. WHITE, and C. H. JONES (*Vermont Sta. Rpt. 1896-97*, pp. 32, 33).—These include analyses of 3 samples of material suspected of being oleomargarine, 4 of maple sirup, 1 each of maple sugar and sap, 5

of adulterated honeys, and 11 of mill feeds, the latter including "wheat by-product," oat feed, flax meal, cream and Atlas gluten meal, middlings, buckwheat hulls, and mixed feed.

### BOTANY.

**Contributions to the life history of *Amphicarpæa monoica*,** ADELINE F. SCHIVELY (*Contrib. Bot. Lab. Univ. Pennsylvania, I, No. 3, pp. 270-363, pls. 18*).—The author has made a very comprehensive study of the life history of this plant, which, as was already known, bears both aerial and subterranean fruits. In the present study it was established that 4 distinct types of pods and flowers were developed, 3 being borne above ground and the other subterranean. The aerial flowers, which are characteristically different, develop different kinds of pods. A dimorphism resulting from the germination of the subterranean and aerial seeds is also established, it being decidedly noticeable in the case of plants grown during the winter and to a less degree in those grown in the open during summer. It was found that the aerial cleistogamic flowers or young pods may be converted into the subterranean forms by burying them in the soil.

**A chemico-physiological study of *Spirogyra nitida*,** MARY E. PENNINGTON (*Contrib. Bot. Lab. Univ. Pennsylvania, I, No. 3, pp. 203-259*).—The author gives the results of a study of the chemistry and physiology of *Spirogyra nitida*, in which some very interesting facts are brought out. The conjugative cells show a widely different chemical composition from the vegetative cells. The action under colored screens modified the chemical composition of the alga according to the rays of light received.

"Violet rays prevented almost wholly the hydration of starch, and soon killed the plant. Blue rays gave an imperfect hydration, but sufficient to preserve life for some time. Starch was not formed in the cells. Green rays caused an active assimilation with a continuous growth and unusual protoplasmic motility. The protoplasm was also in increased quantity. Green light favored the production of crystals, particularly of calcium tartrate. Yellow rays caused elongation of the cells, which contained abnormal quantities of soluble carbohydrate, but no starch, no tannin, and no crystals. The cells were short lived. Orange rays caused a good growth closely approximating the normal. Crystals were not plentiful, however, and the sugar was in rather large quantity. Red rays caused a growth which was even more rapid than that made in white light. Tannin was formed in larger quantities than under the normal conditions."

**On the structure and pollination of the flowers of *Eupatorium* spp.,** LAURA B. CROSS (*Contrib. Bot. Lab. Univ. Pennsylvania, I, No. 3, pp. 260-269, pl. 1*).—The author has made a study of *Eupatorium ageratoides* and *E. caelestium* to determine the question of their pollination. It was found that self-pollination in species of *Eupatorium* is very rare indeed, and that when it does occur the resulting fruits have a very weak germinative capacity. When close pollination by hand was effected a slight increase of good fruits was obtained; but when covered flowers were cross-pollinated the increase was very striking.

**The correlation of growth under the influence of injuries,** C. O. TOWNSEND (*Ann. Bot.*, 11 (1897), No. 44, pp. 509-532).—The author has reported on a series of experiments to test the first effects of injury upon the growth of plants, to determine the effect of a single irritation of short duration, and the time required for such an effect to manifest itself. The well-known effect of the removal of the branches of a tree on the development of other branches or the development of fruit and the disturbance of the roots of garden plants through cultivation are mentioned. The experiments for the most part were conducted with seedlings of *Phaseolus multiflorus*, *Vicia faba*, *Lupinus albus*, *Helianthus annuus*, *Cucurbita pepo*, *Zea mays*, *Avena sativa*, *Hordeum vulgare*, and *Secale cereale*; also with older plants of *Calla* and a few cuttings of willows. A number of experiments were also made with *Phycomyces nitens*. The different experiments are reported upon in detail, and the following summary is given:

“A single irritation produced by cutting or splitting the shoots or roots or removing the leaf tips of seedlings tends to produce a change in the rate of growth of the injured and of the uninjured parts.

“If the injury is slight, signs of an acceleration in the rate of growth will be apparent in from 6 to 24 hours, and will continue for from 1 to several days. If the injury is severe, the acceleration will be preceded by a period of retardation of longer or shorter duration, depending upon the severity of the injury and upon the condition of the plant injured.

“The growth of the stems of older plants is accelerated by removal of a number of the roots or leaves, but is not affected by a slight injury to the roots.

“The roots of older plants as well as of seedlings are more independent than are the stems or shoots.

“The change in the rate of growth of higher plants under the influence of a single irritation begins gradually, reaches its maximum in from 12 to 96 hours, and gradually diminishes until the normal rate is resumed.

“A dilute but continuous atmosphere of ether, or a strong shock of ether of short duration, will produce an acceleration in growth.

“The total variation in the growth of higher plants due to the influence of a single irritation is from 0 to 70 per cent of the normal growth for the same period.

“The growth of sporangium stalks of *Phycomyces* is suddenly and strongly retarded by cutting either the mycelia or another sporangium stalk on the same plant. The growth does not entirely cease, and gradually recovers its normal rate in from 30 to 60 minutes.

“The influence of an irritation due to cutting or other injury is capable of acting through a distance of several hundred millimeters.”

**Periodicity of root pressure,** M. B. THOMAS (*Proc. Indiana Acad. Sci.*, 1896, pp. 143-147).—The author gives in this paper, which is an abstract of a more detailed presentation of the subject, the following general conclusions:

“The periodicity of root pressure seems to be inherent in the plant, and has either been acquired by previous adaptation to environments, or as the results of the action of some constant or periodic changes in the plant. As with the periodicity of growth and other periodic phenomena, it does not always follow that periodic change has not been produced by some constantly or continuously acting agent.

“Root pressure does not seem to have any relation to the previous periodicities of the vital activities of the plant when the top was connected with the roots. The measure of the root pressure seems to be the osmotic activity of the root hairs, and

is probably due to the presence of organic acids and other substances in the rhizoids that show great affinity for water. Although the organic acids increase in the cells at 50 to 60° F., yet their increase does not seem to make any appreciable difference in the periodicity. This is true even when the temperature of the soil is brought up to 55° F., approaching the time of minimum pressure.

“The fact that seems inexplicable is that, when the temperature is raised above the point where the organic acids decompose (60° F.) in most plants, the roots may show an increase in their osmotic activity at the daily period of maximum pressure. The absence of a top to the plant and its consequent loss of periods of maximum and minimum oxidation, which are the real causes of the variation in the quantity of organic acids in the cell, may be the reason for the failure to produce the expected results. The time of periodicity of root pressure is constant in the same genus, but some species may show greater absolute pressure than others. This may be due to accidents in growth, etc. The fact of the periodicity of root pressure seems to be established beyond the possibility of a doubt, and capillarity and similar phenomena can not account for the facts observed.”

**The amount of nitrogen conveyed by red clover to different kinds of soil**, N. PASSERINI (*Bol. Scuola Agrar. Seandiceci*, 1895, No. 3, pp. 102-111; *abs. in Jour. Chem. Soc. [London]*, 72 (1897), No. 421, II, p. 587).—A report is given of experiments with red clover grown in wooden boxes containing 3 different kinds of soil—sandy, clayey, and calcareous. There was a decided loss in nitrogen in the soil at the end of the experiments in the case of the sandy and clayey soils, but a gain in the calcareous soil. The loss is at least in part attributed to a loss of nitrates in drainage and possibly a less active fixation of nitrogen.

**Nitrogen nutrition of the Leguminosæ**, K. VON ROZDEJCZER (*Inaug. Diss., Leipzig*; *abs. in Jour. Chem. Soc. [London]*, 72 (1897), No. 421, II, pp. 586, 587).—A report is given of experiments in which peas were grown in sandy, loamy, and humus soils. There were 3 series of experiments. In the first the pots were unmanured, in the second they were manured with mineral manure and sodium nitrate, and in the third with mineral fertilizer without sodium nitrate. The pots were kept in the open air except during very wet weather, and the amount of nitrogen in the rain and water used was determined.

On taking up the plants the greatest tubercle development was found in the pots which had received chemical fertilizers and in the unmanured sandy soil, the development being slight in the loamy and humus soils and very poorly represented in the pots receiving sodium nitrate. A summary shows the average amount of nitrogen in the soil, seed, and produce, and also the gain or loss at the end of each experiment. A gain in nitrogen was indicated in every series except that of the loamy soil which received the sodium nitrate, in which there was a loss.

The author concludes that with insufficient nitrogen in the soil peas assimilate considerable amounts of free nitrogen, but with an increased supply of soil nitrogen the power of fixing free nitrogen diminishes, the plants utilizing the combined nitrogen of the soil. With rich soils elementary nitrogen is either not utilized at all or in very small quantities. The author states that leguminous crops should be well manured with potash and phosphoric acid.

The morphology of the Blastomycetes, O. CASOGRANDI (*Centbl. Bakt. u. Par.*, 2. Abt., 3 (1897), Nos. 23-24, pp. 634-639; 25-26, pp. 718-722).

A contribution to the study of malate and malophosphate of lime in plants, M. MIRANDE (*Jour. Bot. [Paris]*, 12 (1897), Nos. 1, pp. 6-12; 2, pp. 32-36, figs. 4).

The effect of one-sided applications of nitrogen fertilizer, P. SORAUER (*Ztschr. Pflanzenkrank.*, 7 (1897), No. 5, pp. 287-290).—Comparisons of the different plant tissues are made, to show the effect of the addition of a comparatively large amount of sulphate of ammonia to pots in which fuchsias were grown.

The action of denitrifying bacteria toward some carbon compounds, H. JENSEN (*Centbl. Bakt. u. Par.*, 2. Abt., 3 (1897), Nos. 23-24, pp. 622-627; 25-26, pp. 689-698).

**Fixation of atmospheric nitrogen by dead leaves**, L. DÉTRIE (*Bul. Soc. Cent. Forst. Belg.*, 5 (1898), No. 1, pp. 36-38).

**The proteolytic enzym of Nepenthes**, S. H. VINES (*Ann. Bot.*, 11 (1897), No. 44, pp. 563-584).—The author believes the proteolytic digestion which takes place in pitcher plants is due to an enzym and not to bacteria. In *Nepenthes* he found that fibrin was digested in the presence of 1 per cent of hydrocyanic acid and that the activity of the ferment is retained for several weeks in pure glycerin.

**A new bigeneric hybrid**, S. KORSHINSKY (*Bul. Acad. Impér. Sci. [St. Petersburg]*, 5. ser., 6 (1897), No. 4, pp. 322-324, pl. 1).—A hybrid of *Cucumis melo* and *Citrullus vulgaris* is described.

## FERMENTATION—BACTERIOLOGY.

**The bacteriological flora of the air in stables**, A. W. BITTING and C. E. DAVIS (*Proc. Indiana Acad. Sci.*, 1896, pp. 172-184, pls. 5).—The authors report studies conducted to determine the number of bacteria found in the air of stables, and to determine whether a relationship exists between the number of germs found in air and the sanitary condition of the place. Ten barns and stables were selected, representing different sanitary conditions, and 15 tests of the air were made inside the buildings and a corresponding number in the open air at the same time. The average number of colonies developed per liter from the air inside the stables was 86, as compared with 27 from the outside air. Thirty tests were made by Petri dish exposures for 2 minutes each in the air inside the stables and 15 tests in the open air. The average number of colonies on the plates exposed inside the stables was 174, and 55 on those exposed outside.

It was found that the number of germs per liter of air could not be taken as an index of the sanitary surroundings, as the dust caused by feeding, moving of bedding, currying, etc., have more to do with the number of germs which will be drawn into a Hesse tube or fall on a Petri dish than lack of ventilation has.

Detailed descriptions are given of 18 forms of bacteria collected in the different stables.

**Studies on nitrification**, H. WEISSENBERG (*Arch. Hyg.*, 30 (1897), No. 3, pp. 274-289; *abs. in Chem. Ztg.*, 21 (1897), No. 85, *Repert.*, p. 231).—Studies of the *Bacillus denitrificans* I and II of Stutzer and Burri, or, adopting the nomenclature of Lehmann and Neumann, *B. denitrificans* and *B. stutzeri*, were made under varying conditions in different culture media. It appears from these studies that, as Stutzer and Burri claim, the first of these organisms denitrifies only when acting in symbiosis with other organisms which reduce nitrates to nitrites, such as *Bacillus coli* or *B. typhi*. The second organism, *B. stutzeri*, in comparative tests with *B. pyocyaneum* from different sources behaved like the latter in every case, denitrifying nitrates directly without the intervention of other organisms. In the reduction of the nitrates the oxygen is seized by the organism, the nitrogen escapes, and sodium hydroxid is formed, increasing the alkalinity of the medium. This process is checked by the introduction of a liberal supply of air (oxygen). In

the reduction of nitrates to nitrites the oxygen is not taken up directly by the cells of the organisms. The presence of acids and alkalies checks the action of the denitrifying organisms.

## METEOROLOGY.

**Monthly Weather Review** (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 25 (1897), Nos. 10, pp. 125-170, figs. 2, charts 1; 11, pp. 171-516, figs. 5, charts 9; 12, pp. 519-568, figs. 6, charts 7*).—Besides the usual meteorological summaries, No. 10 contains special articles on Wind and clouds, by M. Brillouin (translated from the French<sup>1</sup>); Climate as a controlling factor in long distance transmission of electrical energy, by A. G. McAdie; Atmospheric electricity, its origin, variations, and perturbations, by M. Brillouin (translated from the French<sup>2</sup>); The area of heavy rainfall in the southern Appalachians, by B. C. Hawkins; Photographic apparatus for measuring the altitudes attained by balloons, by L. Cailletet (translated from the French<sup>3</sup>); and notes by the editor on mountain stations in North Carolina; hydrodynamic equations for the atmosphere; raindrops, their size and rate of fall; atmospheric electricity—Brillouin's theory; hurricanes in the West Indies; altitudes of clouds; origin of the descending gusts of wind; recent earthquakes, and distant cloud banks.

No. 11 contains special articles on A winter barograph curve from the South Pacific Ocean, by R. De C. Ward; and An improved sunshine recorder, by D. T. Maring, and notes by the editor on the kite in France, local climatic changes, the celebration of the semicentennial of the Royal Prussian Meteorological Institution, recent earthquakes, and Weather Bureau station on Mount Tamalpais.

No. 12 contains special articles on A preliminary discussion of certain cyclical changes in India, by W. L. Dallas (figs. 6); and The elec-

trical storms of California, by A. J. Barwick; and notes by the editor on mechanical determination of resultant wind, the meteorological stations of Harvard University, meteorology in the United States Geological Survey, recent earthquakes, electric storms at Sacramento, distant cloud banks, cloudy condensation, cycles in meteorology, water measurements for irrigation, and chinooks in Iowa.

**Meteorology of 1896**, W. S. SWEETSER (*Pennsylvania Sta. Rpt. 1896*, pp. 225-229, 233-246, 251-273).—"The work of the past year has been merely a continuation of the work of the preceding years [E. S. R., 8, p. 754], including the observations usually called for by the United States Weather Bureau upon atmospheric conditions, and also observations upon soil temperature at various depths [see p. 819] and upon the daily duration of sunshine." The annual summary is as follows:

*Summary of meteorological observations, 1896.*

	Year 1896.	Growing season (Apr. - Sept., 1896).
Barometer (inches):		
Mean .....	30.050 .....	
Highest .....	30.861 (Dec. 29) .....	
Lowest .....	28.948 (Feb. 6) .....	
Temperature (° F.):		
Mean .....	49.5 .....	64.2.
Highest .....	93 (Aug. 9) .....	93 (Aug. 9).
Lowest .....	6 (Feb. 17) .....	21 (Apr. 3).
Mean daily range .....	17.7 .....	19.5.
Greatest daily range .....	39 (May 9) .....	39 (May 19).
Least daily range .....	4 (Jan. 24, 25) .....	
Mean daily relative humidity (per cent) .....	81.8 .....	77.3.
Rainfall (inches):		
Total .....	35.28 .....	20.
Greatest monthly .....	5.56 (July) .....	5.56 (July).
Greatest daily .....	2.40 (Sept. 30) .....	2.40 (Sept. 30).
Number of days on which 0.01 in. or more of rain fell .....	132 .....	69.
Mean percentage of cloudiness .....	60.0 .....	55.5.
Number of days on which cloudiness averaged 80 per cent or more .....	138 .....	62.
Average hours of sunshine per day .....		4 h. 59 m.
Wind (miles):		
Total movement .....	25,340 .....	
Maximum velocity .....	28 (Feb. 6) .....	
Greatest daily movement .....	435 (Mar. 2) .....	
Last frost in spring .....		Apr. 23.
First frost in fall .....		Sept. 24.

*Principal periods of crop development.*

Wheat:

  Seeded, September 1-6, 1895.  
  In bloom, June 1, 1896.  
  Ripening, June 12.  
  Cut, July 3.

Corn:

  Planted, May 4.  
  In silk, July 24.  
  Cut, September 11.  
  Husking begun, September 25.

Clover:

  In bloom, May 29.  
  Cut, June 20.

Oats:

  Seeded, April 15-24.  
  Ripening, July 17.  
  Cut, July 20-24.

Potatoes:

  Planted, May 15.  
  Late varieties harvested September 25.

Grass:

  In bloom, June 5.  
  Cut, June 26.

**Floods of the Mississippi River**, P. MORRILL (*U. S. Dept. Agr., Weather Bureau Doc. 143, pp. 79, pls. 61, figs. 3*).—This paper discusses the floods of the Mississippi in general, but gives especial attention to the flood which occurred during the spring of 1897.

“The effort has been made to briefly cover the entire regimen of the river, both in its normal condition and in flood. The physical characteristics of the Mississippi basin and river have been reviewed, and the best data available as to area of watersheds, dimensions, and slope of the main stream and its tributaries are given, largely in tabular form, convenient for reference. The records of the Weather Bureau have been used to determine the normal precipitation for each month and for the year. . . . The resultant downfall of water over the various subdivisions of the grand basin has been computed, and is presented in tables. Normal river stages at various stations have been computed, and are here published for the first time, so far as known. The chart of normal hydrographs drawn from these data is instructive, showing at a glance the annual rise and fall of the Mississippi and its chief feeders. Other facts as to the extreme stages of the rivers, the volume of discharge, and similar matters have been collected from many sources, and are presented in convenient form.

“Having treated of the normal conditions of water supply and drainage throughout the basin, the subject of floods is next considered at some length. The floods occurring during the past 26 years are made the chief subject of study, inasmuch as only during that time are complete and reliable gauge readings available. Six notable flood years are embraced in this period, and for these 6 floods hydrographs have been drawn for several typical stations. The downfall of water from which each flood arose has been computed, and the results are given in tabular form. Corresponding charts of actual precipitation and of the departure from the normal precipitation have also been constructed for each flood, and accompany the report. Through our own observers, and from the investigations of the engineer officers in charge of levee work, a map of the region inundated this year has been prepared, and forms an interesting accompaniment to the paper.”

**The highest kite ascensions at Blue Hill**, S. P. FERGUSON (*U. S. Dept. Agr., Weather Bureau Doc. 145, pp. 4*).—“On September 19, 1897, the kite meteorograph was raised to a height of 2,821 meters (9,255 ft.) above the summit of the Hill, or 3,013 meters (9,885 ft.) above sea level. The highest kite was 40 meters (131 ft.) above the meteorograph, or 3,052 meters (10,016 ft.) above sea level. The height reached by the meteorograph was 510 ft. higher than that reached on October 8, 1896.”<sup>1</sup>

**Meteorological observations** (*Canada Expt. Farms Rpts. 1896, pp. 61, 297, 375, 421-423, 459*).—Notes on the weather and monthly summaries of observations on temperature and precipitation during 1896 at the experimental farms in the different provinces of Canada.

**Meteorological report for 1895**, J. C. RANE (*West Virginia Sta. Rpt. 1895, pp. 50-53*).—Monthly summary of observations on temperature, precipitation, direction of wind, etc., for the period from June, 1894, to April, 1895.

**Meteorological observations**, L. H. MERRILL (*Maine Sta. Rpt. 1896, p. 127*).—This is a summary of observations on temperature, atmospheric pressure, precipitation, and cloudiness during the 6 months ending December 31, 1896. The maximum pressure during this period was 30.6 in., the minimum 29.6 in., the mean 30.14 in. The highest temperature was 74° F., the lowest 22°, the mean 48°.

<sup>1</sup> See also Monthly Weather Review, 25 (1897), No. 9, p. 392.

Monthly reports of the River and Flood Service for September, October, November, and December, 1897, P. MORRILL (*U. S. Dept. Agr., Weather Bureau Docs. 137, pp. 11, chart 1; 144, pp. 11, chart 1; 147, pp. 13, chart 1; 151, pp. 13, chart 1*).—(See also Monthly Weather Review, 25 (1897), Nos. 9, p. 389; 10, p. 434; 11, p. 479; 12, p. 529).

Forest and rainfall, H. A. HAZEN (*U. S. Dept. Agr., Weather Bureau Doc. 140, pp. 7*).—It is claimed in this paper that while forests have “a most important bearing upon the conservation of rainfall” their effect upon precipitation “if there be one, is almost inappreciable. . . . From the evidence already accumulated there would be very little to be gained by a further study of the question.”

Instructions to operators on the United States seacoast telegraph lines, J. H. ROBINSON (*U. S. Dept. Agr., Weather Bureau Doc. 134, pp. 26*).—These lines were “built for the benefit and better protection of commerce at large, in conveying information and warning of approaching storms and summoning aid in cases of marine disaster . . . [and] are, by law, in the charge and control of the Chief of the Weather Bureau, with respect to their maintenance and operation.”

A winter barograph curve from the South Pacific Ocean, R. DE C. WARD (*U. S. Dept. Agr., Weather Bureau Doc. 149, pp. 6, fig. 1*).—A curve obtained with a small-sized Richard Feres barograph during a winter voyage through the Straits of Magellan and upon the west coast of South America as far as Corral, Chile (latitude  $39^{\circ} 52'$  S.; longitude  $73^{\circ} 17'$  W.).<sup>1</sup>

An improved sunshine recorder, D. T. MARING (*U. S. Dept. Agr., Weather Bureau Doc. 148, pp. 15, pl. 1, figs. 4*).—This is a detailed description, accompanied by figures, reprinted from the Monthly Weather Review, 25 (1897), No. 11, p. 485.

The probable state of the sky along the path of total eclipse of the sun May 28, 1900, F. H. BIGELOW (*U. S. Dept. Agr., Weather Bureau Doc. 142, pp. 7, chart 1*).

Instructions governing the corn, wheat, cotton, sugar, and rice region service, J. BERRY (*U. S. Dept. Agr., Weather Bureau Doc. 133, pp. 9*).

## WATER—SOILS.

The rocks and soils of Grenada and Carriacou, J. B. HARRISON (*London: Waterlow & Sons, Ltd., 1896, pp. 1-30, 57-60*).—This is an account of a brief study of the geology, rocks, and soils of these two islands of the Windward group. At present only soils derived from the decomposition of lavas are cultivated. In order to study the changes which have occurred in the course of the disintegration of these lavas and the formation of the soil, bulk analyses were made of the various typical kinds of lavas and of soils which were clearly derived from two of them.

“In the soils from the hornblende andesites it is seen by this method that a very heavy loss of silica has ensued, an apparent increase of over 30 per cent has taken place in the oxids of iron, and that the state of oxidation of the major part of the iron has been changed from protoxid to peroxid; that nearly two-thirds of the manganese oxid, over three-quarters of the lime, one-quarter of the magnesia, eight-ninths of the potash, five-sixths of the soda, and nearly two-thirds of the phosphoric anhydrid have been lost, while the amount of water and organic matters are approximately four times greater than in the rock. The increase in the oxids of iron, which in the part of the soil not dissolved by hydrochloric acid are principally present in the form

<sup>1</sup> See also Monthly Weather Review, 25 (1897), No. 11, p. 484.

of small heavy grains of magnetite, leads to the conclusion that the loss has not been alone by the removal by drainage of the constituents rendered soluble by oxidation and other chemical changes, but largely by the removal of some of the lighter argillaceous products by surface washing, and this view is upheld by the unexpectedly heavy loss of silica.

"In the case of the soils derived from the more basic lavas, augite andesite with olivine and olivine basalt, nearly one-third of the silica has disappeared, the iron oxids have increased by about one-twelfth, approximately one-sixth of the oxid of manganese, four-fifths of the potash, and three-quarters of the phosphoric anhydrid have been lost, while the amount of water and organic matter are approximately four times the original quantity. The most striking losses have been in the lime, magnesia, and soda, of which, in round numbers, 96, 88, and 94 per cent have been lost, respectively. The low increase in the proportions of the heavy iron minerals tends to show that in the soils of this kind selected for comparison but little loss of the lighter products of decomposition has taken place by surface washing. The noteworthy point is the very high rates of loss of the lime, magnesia, and soda of these basic rocks, probably in solution by drainage, showing that the feldspars, the plentiful augite, and the olivine have suffered very complete decomposition during their degradation."

Analyses of 41 typical soils of the Island of Grenada are reported, showing the mineral constituents soluble on digestion with 20 per cent hydrochloric acid at the boiling point for 5 days, and the phosphoric acid and potash soluble in 1 per cent citric acid on digestion for 5 days in the cold.

"[Of these 41 samples] 26 are deficient in phosphoric acid, in many cases the amount present being very low, while in those in which phosphoric acid is present in fair proportions it is as a rule in a state of very low availability, either on account of its being in a very insoluble state in the form of apatite as it occurs in some of the lavas, or from the low proportion it bears to the quantities of alumina and iron peroxid present. Potash is more or less deficient in 19 of the soils. Nitrogen is deficient in 9 only, most of the soils containing very fair proportions of this constituent, and in 3 cases alone could the amount of total lime present be described as low, although in 19 cases the amount of immediately available lime in the form of carbonate appears to be deficient."

A table is given which classifies the soils with reference to their deficiencies in the different constituents, and suggestions regarding the use of fertilizers are made.

Analyses of 6 Carriacou soils are reported. These soils were found to be rather light loams, fertile, and with excellent drainage, but very susceptible to injury by drought. The rainfall of this island is so low as to render the cultivation of the majority of tropical crops necessarily unsuccessful. "The only promising industry for this island appears to one to be the growth of sisal hemp."

**Soil temperatures at different depths**, P. SOLLIED (*Norsk Landmansblad*, 1896, No. 34, pp. 402-405).—The observations of the soil temperatures at different depths at the agricultural schools at Aas and Jönsberg, Norway, commenced in 1892 (E. S. R., 6, p. 199), have been continued, and the results for the year November, 1893, to October, 1894, are given. As before, the monthly averages for the thermometer readings have been calculated. They are given in the following table:

## Soil temperatures at different depths, by months.

Date.	Aas Agricultural College.				Jönsberg Agricultural School.			
	Air temperature.	Soil temperatures at depths of—			Air temperature.	Soil temperatures at depths of—		
		$\frac{1}{4}$ meter.	$\frac{1}{2}$ meter.	1 meter.		$\frac{1}{4}$ meter.	$\frac{1}{2}$ meter.	1 meter.
1893.	Deg. C.	Deg. C.	Deg. C.	Deg. C.	Deg. C.	Deg. C.	Deg. C.	Deg. C.
November .....	-3.0	0.9	1.9	4.8	0.0	0.0	0.0	0.0
December .....	-.5	-.2	.5	2.9	.0	.0	.0	.0
1894.								
January .....	-2.0	-.4	-.1	2.2	-2.9	-1.3	-.5	.8
February .....	-1.9	-.9	-.1	1.9	-3.1	3.0 (?)	1.5 (?)	.5
March .....	1.2	.0	-.1	1.8	-.4	-.7	-.6	.2
April .....	4.7	4.3	3.1	3.4	4.1	.5	-.1	.3
May .....	8.6	9.6	8.4	8.1	6.8	6.4	5.3	3.6

October .....	2.0	6.2	6.9	10.2	-.4	4.7	5.6	7.2

Both places of observation are in the interior of the country, Jönsberg being situated about 80 miles north of Aas.—F. W. WOLL.

**Soil temperatures, W. S. SWEETSER** (*Pennsylvania Sta. Rpt. 1896, pp. 230-237, 274-297*).—Tridaily observations during the growing season (Apr.—Sept.) of 1896, with thermometers at the surface and at depths of from 1 to 24 in., are recorded. The following is a summary of the observations:

## Soil temperatures, April to September, 1896.

Depth.	Highest.	Lowest.	Daily mean.	Mean daily range.	Greatest daily range.
	Deg. F.	Deg. F.	Deg. F.	Deg. F.	Deg. F.
At surface .....	92 (Aug. 15, Sept. 11) .....	27 (Apr. 3) .....	64.9	12.41	26 (Aug. 30).
1 in. deep .....	84 (Aug. 11, 15) .....	30 (Apr. 4) .....	64.0	8.21	19 (June 3).
3 in. deep .....	83 (Aug. 11) .....	32 (Apr. 3, 4, 5, 6) .....	64.3	6.33	12.5 (Aug. 15).
6 in. deep .....	80 (Aug. 9, 11) .....	32 (Apr., 8 days) .....	63.8	4.06	9.5 (Apr. 13).
12 in. deep .....	77 (Aug. 11, 12) .....	32.5 (Apr. 3, 4, 5) .....	62.6	1.50	4.5 (Apr. 13).
24 in. deep .....	72.5 (Aug. 12, 13) .....	33.5 (Apr. 1, 2, 3, 4, 5) ..	60.7	.30	1.5 (June 18).

**Influence of the humidity of the soil on the development of flax, D. N. PRYANISHNIKOV and R. G. TRUBE** (*Izv. Moscow Selskokhoz. Inst., 3 (1897), II, pp. 49-51*).—The object of this experiment was to note, in addition to the size of the yield, the influence of the humidity on the form of the plant, character of branching, and the correlation in the development of the roots, stalks, and grain. Twenty-four experiments, divided into 4 groups, with 20, 40, 60, and 80 per cent of the maximum water capacity of the soil, were made. At the beginning of the experiment the watering was done once a day, but later, when the plants began to evaporate more energetically, they were watered 2 or 3 times a day. The differences observed in the yield were not great. This is ascribed to the fact that the frequent watering (2 to 3 times a day) enabled the plants, though growing under different degrees of humidity, to evaporate nearly equal quantities of water.—P. FIREMAN.

**On the assimilation of the nitrogen of some organic compounds in sterilized media,** D. N. PRYANISHNIKOV and A. N. LYEBYEDYEV (*Izv. Moscow Selskokhoz. Inst.*, 3 (1897), II, pp. 56-58).—The substances selected for experiment were such as may get into the soil with the manure or are formed in the plants themselves under certain circumstances, viz, hippuric acid, urea, leucin, asparagin, and aspartic acid. The results of the experiments may be summed up as follows: (1) None of the substances tested approached  $\text{Ca}(\text{NO}_3)_2$  as an effective source of nitrogen either in the sterilized or nonsterilized media; (2) sterilization in all cases reduced the availability of the nitrogen of the organic substances, in most cases no grain being obtained in sterilized media.—

P. FIREMAN.

**On the oxidation of the ammonia produced by soil organisms,** E. DEMOUSSY (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 3, pp. 253-256).—The transformation of organic nitrogen into ammonia and finally into nitrites and nitrates by the action of the microorganisms of the soil was studied in culture solutions containing organic nitrogen in the form of monomethylamin, trimethylamin, anilin, pyridin, and quinolin. As a result of the action of the microorganisms the nitrogenous organic compounds experimented with were reduced by oxidation to simpler forms, finally yielding ammonia which was converted into nitrous and nitric acids. The more complex the compounds used the slower was their transformation. In the case of the monomethylamin perceptible amounts of ammonia were formed within 4 hours, but in the case of the trimethylamin the formation of ammonia proceeded much more slowly. With anilin barely a trace of ammonia was detected after 18 days. With pyridin 2 months elapsed before any ammonia was detected, while with quinolin barely a trace of ammonia was detected after 4 months.

**The use of vegetation experiments in soil analysis,** H. WILFARTH (*Chem. Ztg.*, 21 (1897), No. 80, pp. 819, 820).—Vegetation experiments are stated to be very valuable means of determining the needs of soils, but it is claimed that present methods of conducting them are as a rule too costly and time consuming.

The following is one method suggested: Take samples of the soil to a uniform depth with a cylindrical sampler (8 to 9 cm. in diameter). Place a definite number of these soil samples in a vegetation pot and prepare for the experiment by adding all the elements of plant food except the one whose amount in the soil is to be determined. It is assumed that the plant grown will take up all of this element that is available. The amount thus taken up is shown by analysis of the crop obtained. In this way the amounts assimilable by different crops with different habits of growth may be determined. From the amount found for each pot it is easy to calculate the amount per acre. Such experiments are recommended simply as checks on field experiments.

To lessen the labor and expense of running pots into and out of glass houses, maintaining a uniform water content, etc., the author suggests that the pots be permanently placed on a platform scale which

registers the loss of weight (water), thus indicating the amount of water which must be added. For protection against excessive rain the author has arranged a large umbrella which opens automatically when the rainfall reaches a certain amount and closes again when the rain is over. The devices used are described.

**The improvement of muck soils,** F. T. SHUTT (*Canada Expt. Farms Rpts. 1896, pp. 188, 189, pl. 1*).—A brief report is given of experiments with peas grown in pots on a typical muck soil. One pot received no fertilizer, one received wood ashes at the rate of 100 bu. per acre, one wood ashes at the rate of 200 bu. per acre, and one wood ashes at the rate of 50 bu. per acre and marl at the rate of 50 bu. per acre.

The results indicate that the soils were much improved in fertility by the addition of potash and lime in form of wood ashes and marl. The wood ashes alone appeared to be very effective.

**On the relative influence of phosphatic fertilizer on various soils and on the solubility of the phosphoric acid contained in these soils in a 2 per cent citric acid solution,** D. N. PRYANISHNIKOV and B. A. SKALOV (*Izv. Moscow Selskokhoz. Inst., 3 (1897), II, pp. 58-61*).—The experiments appear to show that the degree to which soils are affected by phosphatic fertilizer depends to a certain extent upon the amount of phosphoric acid in the soil soluble in a 2 per cent solution of citric acid. The soils poorest in phosphoric acid soluble in this reagent were most reacted upon by the phosphatic fertilizer, while the soils richest in phosphoric acid soluble in 2 per cent citric acid were not at all affected by the fertilizer. The soils with a medium content of such phosphoric acid were influenced to a degree intermediate between the two extremes.—P. FIREMAN.

**Analyses of drinking water,** J. L. HILLS, B. O. WHITE, and C. H. JONES (*Vermont Sta. Rpt. 1896-'97, pp. 31, 32*).—A table gives results of chemical examinations with regard to sanitary condition of 13 samples each of spring and well water, 4 of driven well water, and 8 of water from ponds, etc. Brief directions regarding sampling and shipping samples are also given.

**Analyses of well waters, 1896,** F. T. SHUTT (*Canada Expt. Farms Rpts. 1896, pp. 216-221, fig. 1*).—Analyses with reference to sanitary condition of 44 samples of well water from different parts of Canada are reported and the pollution of wells is briefly discussed.

**Water used for irrigation on the station farm,** J. A. WIDTSOE (*Utah Sta. Rpt. 1897, pp. 30, 31*).—Analyses are reported which show the mineral constituents in samples of the water used for irrigation in 1892, 1894, and 1895.

**Virgin soils of Canada,** F. T. SHUTT (*Canada Expt. Farms Rpts. 1896, pp. 184-188*).—Chemical and partial mechanical analyses of 4 soils with corresponding subsoils from different localities in British Columbia are reported, with descriptions of the samples and the regions from which they were obtained and explanation of terms used in reporting soil analyses.

**The cultivation of sandy soils in Schleswig-Holstein,** TANCRÉ and JORDAN (*Jahrb. Deut. Landw. Gesell., 12 (1897), pp. 196-213*).—A popular article discussing the cultivation and general management of sandy soils.

**The cultivation of sea marshes on the coasts of the North Sea,** AHSBAHS (*Jahrb. Deut. Landw. Gesell., 12 (1897), pp. 182-196*).—In connection with the article mechanical and chemical analyses of these soils are given.

## FERTILIZERS.

**Preservation of barnyard manure**, F. T. SHUTT (*Canada Expt. Farms. Rpts. 1896, pp. 195, 196*).—As supplementary to the experiments on the deterioration of manure kept for one year in a partially closed shed, an account of which was given in the report of the experimental farms for 1895, p. 42 (E. S. R., 8, p. 880), the author analyzed a sample of the manure collected at the end of the experiment. The fresh manure used weighed 8,000 lbs., the rotted manure obtained weighed 2,659 lbs. Comparing the results of the analysis of the rotted manure with the average composition of fresh manure, the following results were obtained:

*Comparison of the composition of fresh and rotted barnyard manure.*

	Nitrogen.	Phosphoric acid.	Potash.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
8,000 lbs. of fresh manure.....	41.6	24.8	60.8
2,659 lbs. of rotted manure (at end of one year).....	23.6	19.5	39.8

In experiments in which finely ground mineral phosphate was mixed with fermenting manure (at the rate of 50 lbs. of phosphate per ton of manure) and kept in glass jars buried in a manure heap from April 29 to August 20 there did not appear to be any "solvent action, or at most a very slight one, on the mineral phosphate exerted by the manure during the process of fermentation."

**Is there a constant relation between the solubility of phosphatic slag in ammonium citrate and the weight of the crop produced?** A. PETERMANN and J. GRAFTIAU (*Bul. Sta. Agron. Gembloux, 1898, No. 64, pp. 5-13*).—An account is given of pot experiments with 11 different slags on oats followed by white mustard in 1896 and on wheat in 1897. Examinations of the slags used showed that all of them contained more than 16 per cent of total phosphoric acid and 75 per cent of fine meal. The solubility of the phosphoric acid in Wagner's ammonium citrate solution varied from 37 to 93 per cent. The free lime determined by repeated extraction of 5 gms. of slag with 150 cc. of a 20 per cent solution of sugar free from carbon dioxide varied from 0.84 to 5.67 per cent. As the following table of maximums and minimums shows, the citrate solubility varied inversely as the free lime and directly as the silica soluble in mineral acids.

*Relation between citrate solubility and free lime and soluble silica in the slags.*

	Per cent.	Per cent.
Calcium oxid (free).....	5.67 (max.)	0.84 (min.)
Silica soluble in mineral acids.....	3.24 (min.)	9.27 (max.)
Citrate-soluble phosphoric acid.....	37.60 (min.)	93.40 (max.)

The variation in citrate solubility is claimed to be due simply to variation in the saturation by the lime of the free citric acid in the reagent. A slag rich in silica is poor in free lime. The citric acid is thus left free to attack the phosphate and a high percentage of citrate solubility is found. A slag poor in silica is rich in free lime and shows a low citrate solubility. This explains why Paturel<sup>1</sup> found that when the acid ammonium citrate was used in excess the citrate solubility of all slags examined was greatly increased, and finally became practically identical.

In the pot experiments with oats, mustard, and wheat, a sandy-clay soil containing 0.65 per cent of phosphoric acid soluble in mineral acids in the cold was used. The results show no constant relation between the citrate solubility and the increase in crop produced or the amount of phosphoric acid utilized by the crop.

**General fertilizer experiments, E. H. HESS** (*Pennsylvania Sta. Rpt. 1896, pp. 143-156*).—This includes a summary of results obtained during 1895 and 1896 in the combined fertilizer and rotation experiments commenced at the station in 1883 (*E. S. R.*, 8, p. 763), and a record of the relative stand and yield of mixed clover and timothy in these experiments during the same period.

In 1895 the yield of hay was higher than the stand noted in May indicated on the plats receiving nitrate of soda, and lower on those receiving sulphate of ammonia. This is attributed to the season, which was dry up to the middle of June and thus probably more favorable to the action of the nitrate of soda than to that of the sulphate of ammonia. The season of 1896 was also dry and it was observed that the yield was lower than the stand indicated on the plats receiving sulphate of ammonia and higher on those receiving dried blood.

In both years the stand of clover decreased and that of timothy increased as the amount of nitrogen applied increased. "The plats receiving yard manure produced more hay than the stand indicated."

With the exceptions noted, the agreement between the stand and the final yield was fairly close.

**Recent researches on reverted phosphoric acid, J. STOKLASA** (*Ann. Agron.*, 23 (1897) No. 12, pp. 588-594).—Laboratory experiments with salts of known composition led to the conclusion that the water-soluble portion of superphosphates never contains acid ferrous phosphate, this salt changing almost immediately upon its formation into di-tri-ferriphosphates of varying composition insoluble in water. The addition of ferrous salts to soluble phosphates results in the formation of di-tri-ferriphosphates unless an excess of free phosphoric acid is present. Acid ferric phosphate may be found in superphosphates only when there is at least 30 per cent of free phosphoric acid present. If this is not the case, the acid ferric phosphate may be transformed into mono-di-tri-ferriphosphate  $\text{Fe}_2\text{O}_3(\text{P}_2\text{O}_3)_2 \cdot 8\text{H}_2\text{O}$ .

<sup>1</sup> *Ann. Agron.*, 22 (1896), p. 497 (*E. S. R.*, 8, p. 681).

It is thus seen that the retrogression of phosphoric acid in superphosphates is very largely dependent upon the free phosphoric acid present. Aluminum salts do not behave like iron salts in superphosphate, but like the salts of lime and magnesia.

Pot experiments with barley on a fertile soil containing 0.63 per cent calcium carbonate and 2 per cent of humus and treated with different phosphates of calcium, aluminum, and iron showed that the effect of the acid phosphates of these elements was almost the same. The tribasic phosphates were about one-half as effective as the acid phosphates. The effect of the normal reverted phosphates was about one-half greater than that of the tribasic phosphates.

These results were obtained with a soil comparatively poor in lime and humus. In a soil containing more than 5 per cent of calcium carbonate, the acid phosphate would be rapidly transformed into tribasic phosphates, while if free phosphoric acid is present it forms normal phosphates.

If the soil contains a large quantity of humus, the reverted phosphates are converted into readily soluble and assimilable forms.

Pot experiments with barley on a soil containing 20.2 per cent of humus and 0.31 per cent of lime showed the reverted phosphoric acid to be in this case almost equal to the water-soluble.<sup>1</sup>

**Are the compounds of phosphorus and sulphur found in moors and which are insoluble in strong acids also present in moor plants?** M. SCHMOEGER (*Landw. Jahrb.*, 26 (1897), No. 4-5, pp. 549-554; *abs. in Chem. Ztg.*, 21 (1897), No. 93, *Repert.*, p. 281).—Determinations were made of the phosphorus and sulphur in moor grasses by treating the fresh and dry plants and the ash of the plants with strong hydrochloric acid. The amounts of phosphoric acid found were: In fresh plants 0.13 per cent, in dry plants 0.228 per cent, in ash 0.267 per cent. Similar results (0.105, 0.212, and 0.243 per cent, respectively) were also obtained by treating the moor soil in the same way, and the author concludes that the difficultly soluble phosphorus compounds of such soils are also present in the plants growing on them. Determinations of sulphuric acid showed a slight increase of this substance soluble in acids on drying, but a decided increase when incinerated.

**Fertilizers—barnyard manure and chemical fertilizers,** L. CAILLE (*Les engrais; le fumier de ferme et les engrais chimiques. Montpellier: Camille Coulet, 1897, pp. 211, figs. 5*).—This is a popular discussion of the subject from the standpoint of French agriculture. The book is divided into three parts—barnyard manure, chemical fertilizers, and formulas for chemical fertilizers. The third part is of especial interest, because it recommends and explains a series of fertilizer formulas adapted to the principal farm crops. The objections to the recommendation of specific fertilizer formulas are explained, but it is claimed that the use of such formulas is preferable to blind use of factory mixed fertilizers.

In preparing these formulas two classes of soils are taken into consideration—cal-

<sup>1</sup> See also *Mitt. Ver. Förd. Landw. Versuchsw. Oesterr.*, 1893, No. 8, Part II, p. 140 (E. S. R., 5, p. 1015); and *Landw. Vers. Stat.*, 45 (1894), p. 161 (E. S. R., 6, p. 626).

careous and noncalcareous soils. On the former muriate of potash is used as a source of potash and phosphoric acid is used in the form of superphosphate. For the latter sulphate of potash and precipitated phosphate are considered best. The organic forms of nitrogen may be used more freely on calcareous soils than on the noncalcareous soils. In the latter case nitrate of soda and sulphate of ammonia in connection with gypsum are recommended.

**Recent investigations on the nitrogen of barnyard manure**, E. HASELHOFF (*Landw. Ztg., Westfalen u. Lippe, 55 (1898), Nos. 2, pp. 14-16; 3, pp. 21, 22*).—A brief summary of the conclusions of Wagner, Maercker, Kühn, and others.

**Swamp muck and pond muds**, F. T. SHUTT (*Canada Expt. Farms Rpts. 1896, pp. 189-195*).—Analyses of 11 samples of muck and 4 samples of pond mud are reported and various suggestions regarding the composting and use of these materials are given.

**The utilization of town sewage by irrigation**, E. HASELHOFF (*Landw. Ztg., Westfalen u. Lippe, 55 (1898), No. 5, pp. 38-40*).—The amount of phosphoric acid, potash, and nitrogen furnished by sewage and that required by different crops are discussed.

**The importance and the utilization of town waste**, E. HASELHOFF (*Landw. Ztg., Westfalen u. Lippe, 54 (1897), No. 51, pp. 442-444*).—A popular discussion of the fertilizing value of night soil, sweepings, refuse from slaughterhouses and cattle yards and from flayers' establishments (*abdeckerei*).

**Clovers as green manures**, F. T. SHUTT (*Canada Expt. Farms Rpts. 1896, pp. 196-200, figs. 4*).—Data relating to the yield and composition of crimson clover, red clover (medium and mammoth), and alfalfa are reported, and notes are given on the assimilation of nitrogen by legumes.

**Insuring the action of fertilizers on light soils**, VIBRANS (*Jahrb. Deut. Landw. Gesell., 12 (1897), pp. 10-15*).—A popular discussion of this subject.

**Utah guano**, J. D. WIDTSOE (*Utah Sta. Rpt. 1897, p. 30*).—Analyses are given of 2 samples of Utah guano. It has about the same potash and phosphoric acid content as Peruvian guano, but much less nitrogen.

**Analyses of fertilizing materials**, F. T. SHUTT (*Canada Expt. Farms Rpts. 1896, pp. 201-207*).—Analyses of 2 samples of wood ashes, 3 of garbage ashes, 1 of bran ashes, 1 of broken oyster shells, and 3 of fish meal are reported, and a compilation of analyses of the principal fertilizing materials is given.

By digesting in 1 per cent citric acid it was found "that 43 per cent of the phosphoric acid and 66 per cent of the potash in maple ashes were brought into solution, and that basswood ashes by this method yielded 22 per cent of their phosphoric acid and 60 per cent of the potash."

**Tabulated analyses of commercial fertilizers**, T. J. EDGE and W. FREAR (*Pennsylvania Dept. Agr. Bul. 33, pp. 42*).—This bulletin contains the text of the State fertilizer law, notes on valuation of fertilizers, and tabulated analyses and valuations of 603 samples of fertilizers examined during the period from August 1, 1897, to January 1, 1898.

**Analyses of miscellaneous fertilizers**, J. L. HILLS, B. O. WHITE, and C. H. JONES (*Vermont Sta. Rpt. 1896-97, pp. 28-30*).—Analyses of 61 samples of fertilizing materials, including home-mixed and factory-mixed fertilizers, acid phosphates, ground bone, nitrate of soda, tankage, muriate and sulphate of potash, wood ashes, limekiln ashes, creamatory ashes, cotton waste, and muck are reported. In 11 samples of wood ashes examined the soluble potash varied from 2.45 to 8.21 per cent and the phosphoric acid from 1.08 to 5 per cent.

**A product similar to Chile saltpeter from Southwest Africa**, H. THOMS (*Jour. Landw., 45 (1897), No. 3-4, pp. 263, 264*).—Analysis of a product found as an efflorescence on stones, especially of overhanging cliffs, and used by the inhabitants in the treatment of a variety of diseases, showed it to be an impure nitrate of soda, the impurities consisting principally of sodium and potassium chlorids, potassium and calcium sulphates, silica, and iron oxid.

The possible injurious effect of perchlorate in nitrate of soda, P. WAGNER (*Jahrb. Deut. Landw. Gesell.*, 12 (1897), pp. 15-19).—The danger of using nitrate containing perchlorate, to which Sjollem<sup>1</sup> has called attention, is discussed, and experiments are reported to show that no injury resulted when the amount of perchlorate present did not exceed 0.5 per cent.

On the value of phosphoric acid in superphosphate and in ground Thomas slag, P. WAGNER (*Jahrb. Deut. Landw. Gesell.*, 12 (1897), pp. 146-150).—A popular discussion.

What value has the phosphoric acid of bone meal for agriculture? SCHULTZ-LUPITZ ET AL. (*Jahrb. Deut. Landw. Gesell.*, 12 (1897), pp. 140-146).—The conclusions of Wagner and Maercker are briefly reviewed, and personal experience is referred to which showed that bone meal is not effective as a source of phosphoric acid on dry, light, sandy soils. It appears to be readily utilized by leguminous plants which are also able in favorable conditions to use crude phosphate to advantage.

Report of experiments with different kinds of crude potash salts, M. MAERCKER (*Jahrb. Deut. Landw. Gesell.*, 12 (1897), pp. 150-154).—Experiments with kainit, sylvinite, muriate of potash, carnallite, and other Stassfurt salts on potatoes and barley are briefly reported. Potash in form of chlorid was taken up by the plants more largely than that in form of sulphate. This is ascribed to the greater diffusibility of the chlorid.

A soil test with fertilizers, H. P. ARMSBY (*Pennsylvania Sta. Rpt. 1896*, pp. 123-143).—A reprint of Bulletin 35 of the station (E. S. R., 8, p. 298).

## FIELD CROPS.

**Results obtained in 1897 from trial plats of grain, fodder corn, and roots,** W. SAUNDERS (*Canada Cent. Expt. Farm Bul.* 29, p. 40, pl. 1).—This work was similar to work previously reported (E. S. R., 8, p. 971). Variety tests with oats, barley, spring wheat, peas, corn, turnips, mangel-wurzels, carrots, sugar beets, and potatoes were made at 5 experimental farms located in different parts of the Dominion, and the results are here reported in tabular form. All crossbred varieties which entered into the experiment were produced at the experimental farms. The results of these tests are briefly noted below, the varieties mentioned as most productive being those which gave the largest average results at all the experimental farms.

*Oats.*—Sixty-three varieties, including 10 crossbred sorts, were sown at the rate of 2 bu. per acre on tenth and twentieth acre plats. Among these, Improved American, Golden Giant, Chevalier O. A. U., Columbus, Mennonite, American Beauty, Early Golden Prolific, Bavarian, Rose-dale, Golden Tartarian, Wallis, and Black Beauty, in the order named, produced the largest crops. The average yield for these varieties was 65.29 bu. per acre.

*Barley.*—Fifteen 2-rowed and 20 6-rowed varieties were tried. The size of the plats and the rate of seeding were the same as in the experiments with oats. The 2-rowed sorts yielding the largest crops were Nepean, French Chevalier, Sidney, Pacer, Canadian Thorpe, and Victor, in the order given. Of these, Nepean, Sidney, Pacer, and Victor

<sup>1</sup> Chem. Ztg., 20 (1896), p. 1002 (E. S. R., 8, p. 762).

are hybrid varieties. The 6 varieties mentioned produced an average of 38 bu. and 27 lbs. per acre.

The varieties of 6-rowed barley which produced the largest average yields at all the experimental farms were Oderbruch, Odessa, Mensury, Rennie Improved, Common, and Petschora, in the order named. The average yield for these varieties was 47 bu. 38 lbs. per acre.

*Spring wheat.*—Thirty-eight varieties, including 17 crossbred sorts, were tested on tenth and twentieth acre plats, being sown at the rate of  $1\frac{1}{2}$  bu. per acre. The largest yields, averaging the results of each variety at all the farms, were obtained from the following varieties, in the order named: Wellman Fife, White Connell, White Fife, Monarch, White Russian, Herisson Bearded, Red Fife, Admiral, Hungarian, Preston, Advance, and Vernon. Of these, Admiral, Preston, Advance, and Vernon are crossbred varieties. The average yield of the 12 varieties was 28 bu. 51 lbs. per acre.

*Peas.*—Forty varieties were tested: King, Early Britton, Bright, Creeper, Archer, Prince Albert, Crown, Prussian Blue, Centennial, Victory, Vincent, and Alma, in the order named, produced the largest crops. The average for these varieties was 29 bu. 7 lbs. per acre. King, Bright, Archer, Victory, Vincent, and Alma are crossbred varieties.

*Corn.*—Twenty-four varieties were planted on uniform soil in rows 3 ft. apart, with the plants 6 or 8 in. apart in the row. The yield per acre was calculated from the weight obtained from 2 rows each 66 ft. long. Selected Leeming, Red Cob Ensilage, Cuban Giant, Giant Prolific Ensilage, Mammoth Eight-rowed Flint, and Mammoth Sweet Fodder, in the order mentioned, yielded the heaviest crops. The average yield for these varieties was 21 tons 1,189 lbs. per acre.

*Turnips.*—Eighteen varieties were under test. Seed was sown "on drills or on the flat." At each farm 2 sowings were made, one 2 weeks later than the other. In general, the early sowings gave the best results. The heaviest crops were obtained from the following varieties in the order given: Prize Winner, Shamrock Purple Top, Halewood Bronze Top, Hartley Bronze, Selected Purple Top, and East Lothian. The average yield for these varieties was 23 tons 1,428 lbs. per acre.

*Mangel-wurzels.*—During this season 18 varieties were under trial. The crop was grown like the turnip crop, and in this case also the earlier sowings gave the best results. The heaviest crops were obtained from the following varieties in the order mentioned: Giant Yellow, Intermediate, Selected Mammoth, Long Red, Canadian Giant, Gatepost, Champion Yellow Globe, and Prize Mammoth Long Red. The average yield of these varieties was 26 tons 1,229 lbs. per acre.

*Carrots.*—Fifteen varieties of carrots were grown like the turnips and mangel-wurzels. The larger crops came from the earlier sown plats. The heaviest crops were produced by the following varieties, in the order named: Giant White Vosges, Green Top White Orthe,

Yellow Intermediate, Improved Short White, Iverson Champion, Mammoth White Intermediate. The average yield for these varieties was 16 tons 115 lbs. per acre.

*Sugar beets.*—This crop was grown like the other root crops. As a rule the earlier plantings produced the best results. Out of 5 varieties Red Top Sugar, Improved Imperial, Danish Improved, and Wanzleben, in the order named, produced the heaviest crops. These 4 varieties yielded an average of 16 tons, 217 lbs. per acre.

*Potatoes.*—Tubers of 98 varieties were cut into pieces with 2 or 3 eyes in each, and planted in rows 25 to 30 in. apart with the sets a foot apart in the row. The yield per acre was calculated from the weight of tubers from 2 rows 66 ft. long. The varieties producing the heaviest yield, taking the average of the results obtained at the experimental farms, as in the case of the other crops, were as follows: Irish Daisy, Clarke No. 1, Seedling No. 7, Northern Spy, Reeves Rose, Lee Favorite, Seedling No. 230, American Wonder, New Variety No. 1, Early Puritan, Brownell Winner, and State of Maine. The average crop of the varieties mentioned was 340 bu. 5 lbs. per acre.

The average yields for the past 3 years of the best yielding varieties of oats, barley, spring wheat, and potatoes are tabulated.

**Experiments with corn**, J. F. DUGGAR (*Alabama College Sta. Bul.* 88, pp. 491-502).—These were similar to experiments conducted at the station the year previous (*E. S. R.*, 8, p. 881). The results are given in tables, and summarized as follows:

“Seed corn from Illinois gave a smaller general yield than seed corn grown in the South.

“In 1897 the most productive varieties were Mosby Prolific, Cocke Prolific, and Renfro.

“Kernels from the middle portion of the ear failed to show any superiority over seed from the tip or butt end of the ear.

“Topping and also cutting corn and curing it in shocks slightly decreased the yield of grain. The combined value of grain and stocks, valuing the stocks at 25 cts. per 100 lbs., was greater by \$2.95 per acre than the value of the grain from the plat where only the ears were harvested.

“When each plant was allowed 15 sq. ft. of space, narrow rows and wide spacing in the drill gave slightly better average results than wide rows and close planting in the drill. Having regard to convenience of cultivation as well as to yield, rows practically 5 ft. apart with plants 3 ft. apart in the drill gave most satisfactory results on poor sandy land.

“Cotton-seed meal alone was the most profitable fertilizer for corn in 1897. Acid phosphate and kainit failed to increase the yield. Cotton seed placed in the ground so late as to germinate had considerable fertilizing value.”

**Meadows and pasture formation and cultivation in the Middle-Eastern States**, J. G. SMITH (*U. S. Dept. Agr., Farmers' Bul.* 66, pp. 24, figs. 9).—This bulletin discusses the commercial value of grasses and their importance as soil builders, describes a number of varieties of grasses and clovers suited for hay and pasture, and outlines the methods of preparing the soil and sowing the seed for the establishment of pastures and meadows.

In considering the grasses as soil builders, the author discusses the function of humus in soil, and infers that a field of turned and rotted turf is in a better condition for cropping than an equal area of long-cropped soil abundantly supplied with commercial fertilizers, but deficient in organic matter. "Turf is indirectly a reservoir of nitrogen, and to cover a field with grass is one of the best ways of increasing the amount of humus in the soil."

Barnyard manure, ground bone, bone meal, fish scrap, tankage, dried blood, bran, cotton-seed meal, peanut meal, and legumes grown as green manures or for soiling purposes, are considered valuable sources of nitrogen in fertilizing grass land. Nitrate of soda is not recommended as a fertilizer for grass lands, because it readily leaches away, often produces bad results when applied in large amounts, and has shown itself to have but little influence on the total amount of nitrogen in a crop of clover or peas. Superphosphate or acid phosphate are recommended as sources of phosphoric acid, and wood ashes, kainit, and tobacco stalks as sources of potash. It is advised to make frequent applications of small amounts of fertilizer on very sandy soils in order to obviate the loss of fertilizing material through washing and leaching. "On such lands, when it can be cheaply obtained, crushed cotton seed, from which the oil has not been extracted, is better than cotton seed meal, the oil acting to retard the rotting of the seed and thus extending the period of usefulness of its nitrogen."

The preparation of the soil, as outlined by the author, consists of plowing from 6 to 9 in. deep and subsoiling to an additional depth of from 6 to 12 in., and then harrowing the ground until the surface soil has been brought to a fine tilth and all weeds destroyed. Fall seeding is considered most desirable. The author recommends sowing the seed broadcast without a nurse crop, going over the field in two directions, sowing one half of the seed at each time; to cover the seed with a light brush harrow, and finally to roll the ground for the purpose of packing the surface to prevent the drying out of the young plants.

Timothy, redtop, orchard grass, meadow fescue, tall oat grass, and Italian rye grass are described as hay grasses; and Kentucky blue grass, Canada blue grass, perennial rye grasses, the bent grasses, and red fescue as pasture grasses; white, red, alsike, and crimson clovers, alfalfa, and sandy vetch are described with reference to their value for meadows and pastures. A number of mixtures of seeds for meadows and pastures are suggested.

**Farm crops at the experimental farm at Brandon, Manitoba,** S. A. BEDFORD (*Canada Expt. Farms Rpts. 1896, pp. 321-347, pl. 1*).—The experiments conducted include variety tests of wheat, oats, barley, corn, peas, grasses, turnips, mangel-wurzels, carrots, sugar beets, and potatoes.

Wheat grown on "back-setting" was quite free from rust, even on low ground, and the grain produced weighed from 60 to 62 lbs. per bu.,

while on other plats the crop was injured by rust and yielded a lighter grain.

Plats of wheat, oats, and barley sown May 15 and 23 produced better yields than those sown earlier and later; oats and barley when drilled produced a greater yield than when broadcasted. The results of experiments with remedies for smut in oats and barley are tabulated. In every case the treated seed gave the largest yield.

Flax was grown to determine the fitness of the fiber. Sowing 80 lbs. of seed to the acre yielded the largest total crop.

Awnless brome grass (*Bromus inermis*) is discussed at some length and methods of culture are recommended.

**Field experiments with small grain and root crops, W. SAUNDERS** (*Canada Expt. Farms Rpts. 1896, pp. 5-60, figs. 8, pl. 1*).—The experiments conducted in 1896 comprised variety tests of peas and sugar beets and variety and fertilizer tests with wheat, barley, oats, corn, mangel-wurzels, turnips, carrots, and potatoes. Crops of horse beans, sunflowers, and buckwheat were grown experimentally. The best results from sowing oats, barley, wheat, and peas at different dates were obtained from the sowings made April 27 in each case.

Flax was sown on different dates and at the rate of 40 and 80 lbs. of seed per acre. In 3 out of 4 cases the plats which received 80 lbs. of seed per acre gave the largest quantity of straw, while those which received 40 lbs. yielded the largest crop of seed. The plats sown May 7 produced the greatest weight of straw, and those sown May 14 the largest yield of seed.

The method of originating varieties of crossbred and hybrid grain is discussed, and a table showing the results of vitality tests of grain and other seed is given.

**The profitable amount of seed per acre for corn, J. M. BARTLETT** (*Maine Sta. Rpt. 1896, pp. 30, 31*).—This is in continuation of work described in the Annual Report of the Station for 1895 (E. S. R., 8, p. 773). The plan of the experiment and the size of the plats were the same as in the previous year. An acre of land was divided into 12 equal plats, which were grouped into 4 sets with 3 plats in a set. The fertilizer applied per acre consisted of 15 two-horse loads of barnyard manure, 250 lbs. of acid South Carolina rock, 100 lbs. nitrate of soda, and 75 lbs. of muriate of potash. Tables show the composition of the crop of 1896 and the yields for each year of the experiment. The results for this season have not changed the relation between the average results for the first 2 years and for the whole period of 3 years. "The average yield per acre of dry matter for the 3 seasons at the several rates of seeding are as follows: Kernels 6 in. apart, 5,699 lbs.; at 9 in., 5,827 lbs.; at 12 in., 5,432 lbs."

**The Irish potato, R. H. PRICE** (*Texas Sta. Bul. 12, pp. 913-923, fig. 1*).—The work reported here consisted of variety and fertilizer tests and experiments in storing the tubers. Notes on second crop potatoes

are given. The soil on which these experiments were conducted is a dark, heavy, sandy clay with an almost impervious subsoil.

A test of 51 varieties, including early, medium early, and late sorts, was made, and the results are given in a table. Each variety is briefly described.

The fertilizer test was made on soil where the previous year the same test with sweet potatoes had been carried on. The largest yield of potatoes was obtained from the application of 300 lbs. of boneblack and 200 lbs. of potassium sulphate per acre. Nitrate of soda in every instance lowered the yield below the average of 3 check plats. These results are identical with those obtained the year before in the fertilizer test with sweet potatoes. Applications of muriate and sulphate of potash proved profitable, and boneblack was found to be the best single fertilizer.

Several methods of storing the tubers were tried with unsatisfactory results. Treating the tubers with Bordeaux mixture or slaked lime, immersing them in a 2 per cent sulphuric acid solution for 15 minutes or an hour, and sprinkling them with lime and sulphur did not satisfactorily prevent decay. Keeping the tubers in barrels in dry sand, covering them 1 ft. deep with soil and giving ventilation, and spreading them out under partial shade and covering them with moist hay about 2 in. deep did not prove satisfactory methods of storing. The best results were obtained by leaving the potatoes in the ground and throwing soil over the rows by means of a plow. By the 1st of September 50 per cent of the tubers had decayed, and during the fall rains many sprouted. Some sound tubers were taken from the rows February 15.

**The composition of potatoes,** J. A. WIDTSOE (*Utah Sta. Rpt. 1896, pp. 22-25*).—The dry matter and starch of a large number of varieties of potatoes grown in 1894 and 1895 were determined. The results are compared with those reported in Bulletin 5 of the station (E. S. R., 2, p. 664). The composition of the potatoes grown in 1894 and 1895 is shown in the following table:

*Composition of potatoes.*

	For 1894.		For 1895.	
	Dry matter.	Starch.	Dry matter.	Starch.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Maximum .....	28.12	22.49	32.47	23.29
Minimum .....	19.74	13.98	15.44	10.17
Average .....	23.39	17.85	22.06	16.39

**The ripening of sugar beets,** J. A. WIDTSOE (*Utah Sta. Rpt. 1896, pp. 25-29*).—From September 22 to November 13, 1896, the amount of total solids and the sugar were determined daily in the juice of sugar

beets grown at the station. The average results are shown in the following table:

*Average results of sugar-beet analyses.*

Date.	Total solids.	Sugar.	Purity.	Mean temperature.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Deg. F.</i>
September 22 .....	18.1	15.4	84.7	57.8
September 28-October 2 .....	18.4	15.7	85.3	61.4
October 5-9 .....	18.9	15.6	82.3	52.9
October 12-16 .....	19.7	16.2	84.5	53.7
October 19-23 .....	19.1	15.9	84.7	53.9
October 26-30 .....	19.1	16.0	84.0	43.8
November 2-6 .....	18.4	15.5	85.3	34.1
November 9-13 .....	17.8	14.8	83.2	34.1

**Variety tests—wheat, oats, and potatoes, E. H. HESS** (*Pennsylvania Sta. Rpt. 1896, pp. 157-163*).—Previous work in this line has been reported (E. S. R., 8, pp. 775, 777). The results for this season and the averages for various periods are given in tables. The army worm injured the oats, destroying the value of this season's test, and the results are not reported.

Thirty-one varieties of wheat were grown on thirtieth-acre plats. The best yielding varieties and the number of bushels produced per acre were as follows: Ontario Wonder, 30.57; Fulcaster, 29.81; Wyandotte Red, 27.99; Royal Australian, 27.75; Mediterranean, 27.57; Currell Prolific, 27.56; Jones Square Head, 26.97; Red Fultz, 26.52, and German Emperor, 26.46. The following are the average yields of the first 6 of a number of varieties tested for 7 years: Reliable, 32.21; Fulcaster, 30.75; Ontario Wonder, 30.22; Valley, 29.89; Wyandotte Red, 29.82, and Currell Prolific, 29.66 bu. per acre. For the varieties tested 4 years the average yields for the first 3 were as follows: Royal Australian, 30.56; Canada Wonder, 29.60; Jones Square Head, 29.11 bu.

Among 30 varieties of potatoes Enormous gave the largest yield, 480.8 bu. per acre. Following this variety were Northern Maine, yielding 410 bu.; Delaware, 384.5; Early May, 375.4; Late Puritan, 367.3; Ben Harrison, 363.8, and New Bovee Seedling, 353.1 bu. per acre. The first 6 varieties tested for 3 years stood in the following order: Early Everett, with an average of 267.3 bu.; New Queen, 262.3; Ben Harrison, 259.9; Freeman, 256.9; Pennsylvania Best, 254.3, and Early A, 253.7 bu. per acre.

**Report of the agriculturist, D. D. JOHNSON** (*West Virginia Sta. Rpt. 1893, pp. 49-61*).—A report of the work of the station for the year ending May 31, 1893. Co-operative experiments were carried on under the supervision of the station in various parts of the State. The experiments consisted of tests of commercial fertilizers in growing corn, wheat, vegetable crops, and potatoes and variety tests of corn, tomatoes, cabbage, sorghum, pumpkins, and squashes.

**Report on the experimental farm for the maritime provinces, G. W. FORREST** (*Canada Expt. Farms Rpts. 1896, pp. 297-312*).—This is a report on the meteorological conditions of the year beginning November 22, 1895, and on experiments with spring wheat, barley, oats, peas, turnips, mangel-wurzels, carrots, sugar beets, pota-

toes, corn, and flax. The greater part of the work consisted of tests of varieties of these different crops. In connection with this early, medium, and late sowings of the grains; fertilizer tests; cultural experiments with corn, and trials of sowing different amounts of flax per acre were made. All results are tabulated.

**Farm crops at the experimental farm, Indian Head, Northwest Territories,** A. MACKAY (*Canada Expt. Farms Rpts. 1896, pp. 377-403, pl. 1*).—Varieties of wheat, oats, barley, peas, grasses, corn, turnips, mangel-wurzels, carrots, sugar beets, and potatoes were tested. Wheat sown April 13 gave better returns than wheat sown later; drilling 2 in. deep was found to be better than drilling either 1 or 3 in. deep, and among the different amounts of seed sown per acre  $1\frac{1}{4}$  bu. gave the largest yield. The cost of growing wheat, oats, and barley at the farm is itemized.

**Farm crops at the experimental farm, Agassiz, British Columbia,** T. A. SHARPE (*Canada Expt. Farms Rpts. 1896, pp. 425-442*).—Different cereal and root crops were tested. Early sowings of wheat, oats, and barley produced better yields than the late sowings. In the experiments of sowing clover with grain the clover seemed to have lessened the weight of the grain harvested.

**New varieties of plants for field culture,** A. DUBOIS (*Jour. Agr. Prat., 62 (1898), No. 3, pp. 93, 94, figs. 2*).—Notes on 1 new variety each of beets, potatoes, and maize.

**The selection of pasture plants,** W. TOOGOOD (*Farmers' Gaz., 56 (1897), No. 52, p. 789*).—A popular article on the methods of establishing pastures.

**Methods of establishing meadows,** G. HEUZÉ (*Jour. Agr. Prat., 62 (1898), No. 5, pp. 181, 182*).—Notes on the making of meadows. Three different grass mixtures are suggested.

**Fodder grasses of the northern hemisphere** (*Agr. Jour. Cape of Good Hope, 12 (1898), No. 1, pp. 3-5, fig. 1*).—Notes on Italian rye grass (*Lolium italicum*). The chemical analysis of hay is given, and methods of sowing and harvesting are suggested.

**Notes on varieties of vetches,** E. QUASTHOFF (*Deut. Landw. Presse, 25 (1898), No. 7, p. 73*).

**The velvet bean,** E. W. SHANIBARGER (*Florida Farmer and Fruit Grower, n. ser., 10 (1898), No. 4, p. 54*).—A popular article on the velvet bean.

**The grass-seed industry in New Zealand** (*Farmer's Gaz., 57 (1898), No. 2, p. 17*).

**German grass-seed production,** WITTMACK and O. ERNST (*Jahrb. Deut. Landw. Gesell., 12 (1897), pp. 164-181*).

**Fertilizing constituents in prickly comfrey,** F. T. SHUTT (*Canada Expt. Farms Rpts. 1896, p. 201*).—An analysis of this plant, showing the water, organic matter, total ash, and the nitrogen, phosphoric acid, and potash, is reported.

**Manuring of potatoes** (*Landw. Centbl. Posen, 25 (1897), No. 49, p. 299*).—A popular article.

**Sugar cane,** W. C. STUBBS (*Baton Rouge: State Bureau Agriculture and Immigration, 1897, vol. 1, pp. 208, figs. 28*).—This is the first volume of a treatise on the history, botany, and agriculture of sugar cane, and the chemistry and manufacture of its juices into sugar and other products. This volume treats of the history, botany, and agriculture of the plant.

**Sugar-beet experiments in Arizona,** R. H. FORBES (*Arizona Sta. Bul. 26, pp. 15*).—This is a report on cooperative experiments with sugar beets in 1897. In most cases the Kleinwanzlebener and Vilmorin varieties were grown. The former were richer in sugar content and showed a higher coefficient of purity than the latter. Beets grown after alfalfa gave better results as to richness and purity than those grown on a virgin soil.

**The breeding of grains in Russia** (*Mitt. Deut. Landw. Gesell., 1898, No. 3, Sup., pp. 17-19*).

**The growing of malting barley** (*Queensland Agr. Jour., 1 (1897), No. 6, pp. 433, 434*).—Hints on harvesting the crop.

**Results of experiments with cereals,** F. MADDOX (*Notes and Results on Agricultural Experiments, Tasmania, 1897, pp. 1-71, figs. 96*).—The work reported here consisted mainly of culture and fertilizer experiments and variety tests with wheat

carried on for a number of years. Analyses of cereal, root, and forage crops are given.

**The effect of nitrogen of cow, horse, and sheep manure in a cultural experiment with oats,** G. RUDOLF (*Fähling's Landw. Ztg.*, 47 (1898), No. 2, p. 58).—An article discussing the results obtained in fertilizer experiments by Wagner, Maercker, Kühn, and other investigators.

**The grading of wheats,** N. A. COBB (*Agr. Gaz. New South Wales*, 8 (1897), No. 12, pp. 855-859, pls. 6).—Twenty-eight varieties of wheat were graded into 7 grades by means of sieves with meshes varying from 2 to 3.25 mm. The work of grading is described and the value of the results pointed out. The variety Algerian ranked first in percentage of large grains.

**Comparative variety test of summer wheat** (*Jahresber. Agr. Bot. Vers. Stat. u. Samenprüf. Austalt, Hamburg*, 8 (1898), pp. 8, 9).—A report on 6 varieties. Beseler verbesserter Kolbenweizen gave the best yield. Noe produced the heaviest grain, having also been grown from the heaviest seed. The average number of spikelets in the head was greatest for this variety.

**Judging of the milling qualities of prize wheats at shows, etc.,** F. B. GUTHRIE and E. H. GURNEY (*Agr. Gaz. New South Wales*, 8 (1897), No. 12, pp. 860-865).—The authors recommend the determination of (1) appearance, (2) weight per bushel, (3) ease of milling, (4) percentage of flour obtained, (5) color of flour, (6) percentage of gluten in flour, (7) strength of flour (in quarts of water per sack of 200 lbs. flour). They report the examination of a number of samples of wheat by this method.

**Concerning the conditions under which the volume weight of wheat furnishes a means of judging of its quality,** F. SCHINDLER (*Jour. Landw.*, 45 (1897), No. 1, pp. 61-78).

**Distribution of grain, potatoes, forest trees, etc.,** A. MACKAY (*Canada Expt. Farms Rpts.* 1896, pp. 419-421).—The distributions made in the provinces of Assiniboia, Alberta, and Saskatchewan are tabulated.

## HORTICULTURE.

**Orchard notes,** W. M. MUNSON (*Maine Sta. Rpt.* 1896, pp. 64-83).—A statement of the condition of the orchard at the station is given. No conclusions are drawn, the statement being merely preparatory to a future report. Notes are given on the condition of 57 varieties of plums. The most promising varieties are Duane Purple, German Prune, Hudson River Purple Egg, Imperial Gage, Lombard, McLaughlin, Pond Seedling, Smith Orleans, and Washington. A table is given showing the condition and growth of 34 varieties of apples in 1896, the habit of the trees, and their age at first fruiting. Notes are given on 9 of the less common of these varieties. Notes are also given on 54 varieties of Russian apples, of which the following are considered most promising: Aport, Arabskoc, Golden Reinette, Hiberna, Lead Apple, Longfield, Russian Gravenstein, and Vargulek. The behavior of a number of varieties of Russian apples grown in Aroostook County, Maine, is recorded in tables and brief notes.

**The cherry in Delaware,** G. H. POWELL (*Delaware Sta. Bul.* 35, pp. 23, figs. 9).—This is a popular bulletin treating of the extent of the cherry industry in Delaware, the classification of the cherry, and such practical considerations as soil, location, propagation, planting, cultivation, handling the crop, profits, varieties, diseases, and injurious insects. The fruit of a number of varieties of cherries is illustrated.

Cherry culture in Delaware is limited to dooryards and gardens, but the author believes that it could be profitably extended. The sour cherries succeed in all parts of Delaware, but the sweet cherries can be grown profitably only in a small portion of the State. Brown rot is the most destructive fungus disease and the black aphid and curculio are the worst insect enemies. The author believes that sun scald and bursting of the bark are favored by nitrogenous fertilizers, late fall growth, and exposed trunks. He therefore recommends the use of trees with low spreading heads, the selection of soils that do not favor too vigorous wood growth, and the adoption of such cultural methods as tend to early maturity of wood.

**Winter protection of the peach,** J. C. WHITTEN (*Missouri Sta. Bul.* 38, pp. 140-159, figs. 5).—Winterkilling of the fruit buds of the peach is a very serious drawback to peach culture in the State. In regard to the causes of winterkilling, the author believes that other conditions than mere cold weather are often responsible, since peaches frequently withstand a temperature of  $-10$  to  $25^{\circ}$  F. with little injury. Trees are made more susceptible to injury from cold by imperfect ripening of the wood and buds, due to a late autumn growth induced by warm weather and rains following the dry weather of August. Sudden changes of temperature, either freezing or thawing, is considered more injurious than gradual changes. The most common cause of winterkilling of peaches in the State is the growth of buds during warm weather in winter, which renders them very susceptible to injury from subsequent freezing. The peach is easily stimulated into growth by the warm weather, which often occurs as early as February.

Various means of protecting peach buds from winterkilling have been tried at the station. Of these the effect of whitening the trees and buds has received most attention. In the winter of 1895-'96, a row of young trees running diagonally across the orchard and 4 older trees were sprayed with lime whitewash. The winter was remarkable for its changeable temperatures. During warm periods the unwhitened buds grew perceptibly before any swelling could be detected in the whitened buds. Longitudinal sections of whitened and unwhitened buds taken March 20 showed that in all cases the unwhitened buds had made considerable more growth than whitened ones and that in many cases their pistils were injured. Whitened trees bloomed about one day later than the unwhitened ones. It is thought that the difference in time of blossoming was much less than it would have been in a normal season; the weather became suddenly warm with a dry wind at blossoming time, forcing all varieties into bloom at nearly the same time. Only 20 per cent of the flowers that opened on the unwhitened trees were uninjured and only a few of these set fruit. On the whitened trees 80 per cent of the flowers were perfect and more fruit set than on the unwhitened trees.

In the winter of 1896-'97 the same trees were again whitened. A number of illustrations are given of both whitened and unwhitened

twigs, showing the condition of the buds at various times during the winter and spring. Early in March buds of unwhitened trees were perceptibly swollen, while whitened ones were still dormant. In the middle and last of March the unwhitened buds were much more swollen than the whitened ones. Early in April the unwhitened ones were nearly ready to open, while the others were much less advanced. The unwhitened buds opened from 2 to 6 days earlier than the others. Rivers Early peaches set very abundantly and about equally on whitened and unwhitened trees. Whitened trees of Heath Cling, Silver Medal, and Wonderful varieties set more fruit than the unwhitened ones.

At first a common lime whitewash was used, but it washed off badly in rainy weather. A whitewash of lime with one-fifth skim milk added to the water and 1 lb. of salt per bucketful proved more satisfactory. The whitewash was applied with a spray pump. Four sprayings during winter and spring were sufficient, 2 sprayings being given to begin with to insure a thorough whitening. About half a bucketful of whitewash was used per tree at each spraying. The author states that the entire expense of the 4 sprayings need not exceed 10 cts. per tree. A note is given on the use of copper sulphate applied with the whitewash as a fungicide.

In order to study the relative absorption of heat by the different colors, 4 dairy thermometers, having their bulbs wrapped in green, purple, black, and white muslin, and 1 thermometer with its bulb naked, were exposed to the sun, being hung about 5 ft. from the ground in the orchard. Readings were taken at various times in bright sunshine during February. The thermometers were then removed to the south side of the building, their wrappings removed and placed over them, forming a screen 1 ft. square. Readings were taken during bright weather in the latter part of March. The temperatures recorded are given in tables. The darker the color of the cloth the higher the temperature reached.

In April readings were taken with 4 standard thermometers hung in the open air. The bulbs and such portions of the tubes as could be covered without hindering the taking of readings were coated with whitewash. For 3 of the thermometers the whitewash was colored with anilin dyes; in one case green, in one purple, and in one black. A table is given showing the readings taken. The darker colors absorbed much more heat than the lighter ones. A difference in temperature of 10 to 15° was frequently shown between the white and the purple bulbs, and once in very bright sunshine the difference ran as high as 21°. This difference shows how whitening the green and purple twigs of peaches tends to keep them dormant during warm days of winter.

In the winter of 1895-'96 a few peach trees were protected by drawing the limbs together with a rope, covering them with cornstalks, and binding the whole into a bundle. About 80 per cent of the fruit buds

thus protected were uninjured, while only about 20 per cent of the unprotected buds came through the winter without injury. The covered trees blossomed 2 days later and remained in bloom several days longer than the others. Some of the trees were uncovered at blossoming time and others later, one tree being left until nearly 3 weeks after blossoming. Fruit had set well under the cover except near the top, where the limbs were bound closely together. With young trees the protection is about as easily and cheaply applied and about as effective as whitening, but can not be used as readily with old trees.

Shading 4 trees with canvas hay caps proved about as effective as whitening or covering with cornstalks. For young trees the expense is about equal to whitening, but for old trees the canvas would be too expensive.

Covering the trees with board sheds was tried during 2 winters. Posts were set at the outer ends of the branches, rafters placed on them to meet over the center of the tree, and fence boards fastened an inch a part on the top and part way down the sides. These sheds furnished by far the most effective protection to the trees. Trees thus protected set fruit very well in the spring of 1896 and were not severely injured by either the cold of winter or the hot, dry winds of spring. In the spring of 1897 the buds did not start until the normal blossoming time, the trees blossoming 4 to 5 days later than unprotected trees and 1 day later than whitened ones. They remained in blossom longer and set much more fruit than any other trees of the same varieties in the orchard. The sheds were left over the trees until the middle of May. Almost no fruit dropped from the protected trees, while a good deal dropped from the unprotected ones. Though this method was the most effective one tried, it is considered too expensive for use except in rare instances. The cost for lumber was about \$2 per tree and the cost of building and taking down the sheds 80 cts., making the cost about \$1 per tree each year.

**The cultivation and management of the peach,** J. C. WHITTEN (*Missouri Sta. Bul. 38, pp. 159-164*).—Notes are given on location, fertilizers, soil, planting, cultivation, pruning, thinning fruit, spraying, varieties, etc., the directions given being based on experiments at the station and observations throughout the State. The author recommends the following varieties, named in the order of ripening: Southern Early, Mountain Rose, St. John, Reeves Favorite, Champion, Family Favorite, Foster, Elberta, Mrs. Brett, Wheatland, Oldmixon Free, Oldmixon Cling, Gaylord, Crawford Late, Stump, Smock, Piquette Late, and Salway.

**Problems in plum pollination,** F. A. WAUGH (*Vermont Sta. Rpt. 1896-'97, pp. 87-98, 124-133, figs. 6*).—This is a continuation of work reported in Bulletin 53 of the station (E. S. R., 8, p. 598).

*Self-sterility* (pp. 87-89, 124-125).—In 1897 a large number of blossoms of 56 varieties of various classes of plums in orchards at Denton, Maryland, were protected from cross-pollination by inclosing them in

paper sacks. A table is given, showing for each variety the number of blossoms covered, the number of fruits produced from covered blossoms, and the setting of fruits from unprotected blossoms. The following is a summary of the results:

*Record of protected blossoms.*

Groups.	Varieties included.	Blossoms covered.	Fruit set.
Japanese .....	3	478	0
Americana .....	18	1,709	1
Nigra .....	2	188	0
Miner .....	5	462	1
Wayland .....	6	856	1
Wild Goose .....	11	1,316	0
Chicasaw .....	11	1,419	2
Total .....	56	6,428	5

The author believes that these results indicate the self-sterility of all classes and varieties of native plums and of some Japanese plums.

*Natural adaptations for cross-pollination* (pp. 89-91, 126-133).—Of the various modifications of flowers by which self-pollination is rendered more difficult, those found most common in case of plums are defective pistils, long styles, and proterogyny. A table is given showing the frequency of these modifications in case of a large number of varieties of the different groups of plums in various localities during the past 2 years. The average percentages of defective pistils in the various groups of plums were as follows: Domestica group, 4.3 per cent; Japanese, 11.2; Americana, 21.2; Nigra, 17; Miner, 1.9; Wayland, 10.5; Wild Goose, 19.8; Chicasaw, 10.5; Hybrids, 18.1. The author considers defective pistils to be dependent upon the physiological character of the plant, variety, or species, on the age and health of the tree, and on the storage of food materials. The effect of the health of the tree on the percentage of defective pistils was well shown with Burbank plum, the pistils of a healthy tree being 2 per cent defective, and of a tree dying from the effect of brown rot fungus 58 per cent defective. As to the storage of food materials the author says: "Repeated observations have shown that buds so situated upon a branch as to command a relatively large storage of food give, as a rule, large blossoms, large ovaries, and perfect pistils; while other buds less favorably situated on the same twigs develop sickly looking blossoms with pistils weak or wanting. Any condition of an entire tree which prevents the normal storage of food materials in buds and branches is likely to show in defective pistils at the next blossoming season." A tree of Wolf Seedling No. 4, which bore much too large a crop in 1896, had not a perfect blossom in 1897.

*Pollination affinities of varieties and species* (pp. 91, 92).—A number of crossing experiments were made to determine what varieties are best adapted to pollinate certain other varieties, but the results are considered by the author to be too meager and contradictory to justify conclusions.

*Blossoming seasons of plums* (pp. 92-98).—The time of blossoming and duration of blossoming period of 176 varieties of plums is shown in a chart, the varieties being arranged in the order of their time of blossoming. The chart represents the average blossoming season in the latitude of Denton, Maryland, observations made in orchards there being taken as a basis for the chart, and supplemented by data secured from orchards representing all sections of North America. The duration of the blossoming season of plums is 4 or 5 weeks in the extreme south, and becomes gradually less northward, being but 9 or 10 days in northern Vermont. The average duration for each variety varies from 5 or 6 days in the extreme south to 2 or 3 days in the extreme north. Given varieties do not always blossom in the same order in different localities, or even in different seasons in the same locality. The author believes, however, that these variations are not common enough to affect seriously the reliability of the general averages. The date of blossoming of 8 varieties of plums at Denison, Texas, and Ottawa, Ontario, in 1896 and in 1897 are tabulated, to show the extremes of the blossoming periods in America.

**Classification of plums**, F. A. WAUGH (*Vermont Sta. Rpt. 1896-297*, pp. 98-106).—The classification presented in this article gives the opinion of the author and J. W. Kerr, of Denton, Maryland, on the relationships of the cultivated varieties of plums. The following groups are recognized: *Domestica* (*Prunus domestica*), *Japanese* (*P. triflora*), *Americana* (*P. americana*), *Nigra* (*P. americana nigra*), *Minor* (*P. hortulana*), *Wayland* (*P. hortulana*), *Wild Goose* (*P. hortulana*), *Chicasaw* (*P. angustifolia*), and *Marianna* (probably hybrids). The affinities of these groups are discussed and the varieties referred to each group are noted.

**The preservation of fruits by vapor of alcohol**, F. A. WAUGH (*Vermont Sta. Rpt. 1896-297*, pp. 111-116).—A number of experiments in keeping various fruits are reported. In addition to tests with alcohol, dilute formalin and "platinum waste recovery fluid" were used in one case. The results were mostly negative. The author concludes that vapor of alcohol in a closed space will prevent more or less the growth of fungi and bacteria which usually cause decay but to be effective it must be present in considerable quantities, in which case the fruits, especially those with soft flesh, absorb enough alcohol to render them very disagreeable to the taste. The fruit deteriorates in color and texture and processes of decay other than those due to fungi and bacteria seem to be hastened. The method seems best adapted to keeping grapes but may be of some value for preserving other fruits, as strawberries and raspberries, for a very short time.

**Report of the horticulturist of the experimental farm for the Maritime Provinces**, W. S. BLAIR (*Canada Expt. Farms Rpts. 1896*, pp. 313-319).—Brief notes are given on a number of fruits, vegetables, and ornamental plants. In most cases the notes are accompanied by lists of varieties which are considered most desirable.

**Coffee culture in the Hawaiian Islands**, W. HAYWOOD (*U. S. Consular Rpts.*, 1898, No. 209, pp. 139-164).

**Planting camphor seed**, E. RUMLEY (*Florida Farmer and Fruit Grower*, 10 (1898), No. 4, p. 51).—Popular directions for germinating camphor seed, and subsequent transplanting.

**Asparagus culture**, P. GHERVIN (*Bul. Dir. Agr. et Com.*, 3 (1898), No. 6, pp. 57-62).

**Cabbages**, H. P. GOULD (*Maine Sta. Rpt. 1896*, pp. 145-150).—Reprint of Bulletin 24 of the station (E. S. R., 8, p. 48).

**Growing celery in beds**, J. CRAIG (*Canada Expt. Farms Rpts. 1896*, p. 178).—A brief note on the relative merits of beds and rows for growing celery on a small scale. A tabular statement of the yield of 8 varieties of celery grown in beds is given.

**Lettuce forcing**, W. BRENNECKE (*Amer. Gard.*, 19 (1898), No. 161, Sup., p. 1).—A prize essay on the forcing of lettuce.

**Lettuce forcing**, D. S. LINCOLN (*Amer. Gard.*, 19 (1898), No. 161, Sup., p. 2).—A prize essay.

**The essentials of lettuce forcing; subirrigation**, W. STUART (*Amer. Gard.*, 19 (1898), No. 161, Sup., pp. 4-6).

**Various systems of lettuce forcing**, P. H. DORSETT (*Amer. Gard.*, 19 (1898), No. 161, Sup., pp. 3, 4, figs. 3).

**New melons** (*Wiener Illus. Gart. Ztg.*, 22 (1898), No. 1, pp. 28-30, figs. 4).—Descriptive notes and illustrations of 4 new melons.

**Mushroom culture in France**, C. REPIN (*Garden*, 53 (1898), No. 1368, pp. 99-105, figs. 6).—A reprint from *Revue Générale des Sciences*.

**Reference list of publications relating to edible and poisonous mushrooms**, JOSEPHINE A. CLARK (*U. S. Dept. Agr., Library Bul.*, 20, pp. 16).—The list contains references to some 300 publications.

**Garden peas**, T. A. SILARPE (*Canada Expt. Farms Rpts. 1896*, pp. 175-177, 442, 443).—Variety tests of 16 varieties of peas at the experimental farm for British Columbia and 101 varieties at the central farm.

**Peas and sweet corn**, H. P. GOULD (*Maine Sta. Rpt. 1896*, pp. 154-158).—Reprint of Bulletin 27 of the station (E. S. R., 9, p. 231).

**Notes on winter gardening**, W. M. MUNSON (*Maine Sta. Rpt. 1896*, pp. 84-108, pls. 2, figs. 5).—This is a popular article dealing with construction and management of cold frames, hotbeds, and forcing houses; methods of heating, watering, etc.; and forcing of lettuce, tomatoes, cucumbers, radishes, beans, asparagus, and rhubarb.

**Vegetables, flowers, and fruits**, A. MACKAY (*Canada Expt. Farms Rpts. 1896*, pp. 403-413).—A report of variety tests of a considerable number of varieties of vegetables, fruits, and flowers at the experimental farm for the Northwest Territories.

**Experiments with fruits, vegetables, and ornamental and forest trees**, S. A. BEDFORD (*Canada Expt. Farms Rpts. 1896*, pp. 352-373).—This is a report of extensive variety tests at the experimental farm for Manitoba. The data are given in tables and brief notes.

**Keeping qualities of apples**, J. CRAIG (*Canada Expt. Farms Rpts. 1896*, p. 146).—A number of varieties of apples packed in boxes or baskets were kept in a dark cellar having a temperature of 35 to 40° F. during January, February, and March, and of 45° F. and greater in April and May. For a short time in January the temperature of the cellar was 26° F. and the apples were frozen. In the latter part of May the percentages of sound fruit of the various varieties were as follows: Ben Davis 100, Orange 93, Wagener, 88, Ralls Genet 82, Wine Sap 82, Walbridge 73, Green Sweet 72, Crimean 62, Lawver 49, Bombarger 44, Duke of Connaught 42, Hardy 34, Swayzie 31, Pewaukee 20, Watterson No. 3 20, Salome 20, Fameuse 12, Quaker Beauty 4, and Hardisty, Haas, Gideon, McIntosh Red, and Anisovka 0.

**Varieties of apples**, J. CRAIG (*Canada Expt. Farms Rpts. 1896*, pp. 125-135, figs. 6).—Notes on a number of varieties.

**Evaporating apples**, J. CRAIG (*Canada Expt. Farms Rpts. 1896*, pp. 160-163).—Data as to the relative merits of different varieties of apples for evaporating.

**Improvement of the sand cherry, *Prunus pumila*, J. CRAIG** (*Canada Expt. Farms Rpts. 1896, pp. 123, 124, figs. 2*).—A brief note.

**Olive culture in California, H. G. TINSLEY** (*Bul. Dir. Agr. et Com., 12 (1897), No. 5, pp. 297-301*).

**Relative hardness of fruit buds of peaches and plums, J. CRAIG** (*Canada Expt. Farms Rpts. 1896, pp. 153-158*).—The results of an investigation to ascertain the relative amount of winter injury sustained by various varieties of peaches and plums throughout Ontario are given, together with a brief discussion of the effect of frost on vegetable tissue. A preliminary and tentative grouping of the varieties according to the hardness of their fruit buds is given.

**Pears, plums, and cherries, J. CRAIG** (*Canada Expt. Farms Rpts. 1896, pp. 135-141*).—Tables are given showing the varieties of pears, plums, and cherries planted at the central experimental farm since 1888; the varieties living, the varieties dead, and the causes of their death.

**The peach industry in Pennsylvania, G. C. BUTZ** (*Pennsylvania Sta. Rpt. 1896, pp. 85-111, pls. 2, figs. 14*).—A reprint of Bulletin 37 of the station (E. S. R., 9, p. 351).

**Report on fruits at Huntington, E. A. BENNETT** (*West Virginia Sta. Rpt. 1893, pp. 19-21*).—Notes on apples, cherries, grapes, Russian fruits, and pecans.

**Fruit notes, T. A. SHARPE** (*Canada Expt. Farms Rpts. 1896, pp. 443-458*).—Descriptive notes are given on a large number of varieties of the various fruits grown at the experimental farm for British Columbia.

**Seedling fruits, J. CRAIG** (*Canada Expt. Farms Rpts. 1896, pp. 141-146*).—Information regarding 31 varieties of seedling apples, 6 of plums, 2 of peaches, and 1 each of gooseberries and currants. A number of the more promising seedlings are given a more extended description.

**Pruning deciduous fruit trees, T. H. RAMSAY** (*Pacific Tree and Vine, 14 (1898), No. 47, pp. 138, 139*).

**A new grafting machine, F. A. WAUGH** (*Vermont Sta. Rpt. 1896-'97, pp. 122, 123, fig. 1*).—A test of a new grafting device invented in France is reported.

**Root killing of fruit trees, J. CRAIG** (*Canada Expt. Farms Rpts. 1896, pp. 147-153*).—A discussion of the use of hardy stocks and cover crops to prevent winter killing of the roots of trees and a record of results obtained with various stocks and cover crops. Mammoth clover gave the best results as a cover crop. Alfalfa and crimson clover were next best. Cowpeas and soy beans were of little use.

**Mulching to retard blossoming of large and small fruits, J. CRAIG** (*Canada Expt. Farms Rpts. 1896, pp. 158-160, figs. 2*).—Apples, cherries, plums, gooseberries, currants, and strawberries of various varieties were mulched with strawy manure about March 15, when the ground was deeply frozen and covered with 8 to 12 in. of snow. Others of the same varieties were left unmulched for comparison. A table is given comparing the time of leafing and blossoming of the mulched and unmulched plants. The mulch did not retard leafing and blossoming, except in the case of the strawberries, the tops of which were of course covered. The author concludes that keeping the roots frozen does not affect the time of leafing and blossoming of plants whose tops are unprotected.

**Experiments in cross-fertilizing to produce fruits suitable for the Canadian Northwest, W. SAUNDERS** (*Canada Expt. Farms Rpts. 1896, pp. 61-66, figs. 4*).—Notes on the progress of work in originating hardy varieties of fruits.

**Cranberries, J. CRAIG** (*Canada Expt. Farms Rpts. 1896, pp. 120-122, fig. 2*).—Notes on cranberries and cranberry culture in Canada.

**Raspberries, J. CRAIG** (*Canada Expt. Farms Rpts. 1896, pp. 118, 119, fig. 1*).—An experiment with 17 varieties of red raspberries is reported. Plants that were given winter protection by covering with soil were less injured by winterkilling and yielded more than unprotected plants. Summer pruning, pinching back when 15 to 20 in. high, decreased the yield.

**The grape, J. CRAIG** (*Canada Expt. Farms Rpts. 1896, pp. 103-118, figs. 3*).—Notes on the botanical characters, propagation, cultivation, pruning, training, and varieties of grapes, with tabular data regarding 167 varieties grown at the central experimental farm.

**Practical advice in regard to hybridizing grapes, P. CASTEL** (*Prog. Agr. et Vit., 29 (1898), No. 5, pp. 137-147, figs. 9*).—This is one of a series of articles on hybridizing grapes, the present article treating of the saving, care, and sowing of the seeds. In the course of the paper the author notes some observations on the immediate effect of cross-pollination. Pollen from various sources had no immediate effect on the color or form of the fruits resulting from its use. The seeds of these fruits, on the other hand, were greatly modified in form and resembled the seeds of the varieties which furnished the pollen for crossing. Flowers of the Herbeumonts d'Aurelle grape crossed with pollen from the Othello, Alicante-Bouschet, and varieties of *Vitis riparia* and *V. rupestris*, produced seeds which so resembled those of the varieties from which the pollen was taken that the latter could be readily determined by an inspection of the seeds.

**New stocks for calcareous soils, P. GERVAIS** (*Prog. Agr. et Vit., 29 (1898), No. 5, pp. 132-136*).—Notes on some hybrid grapes used on calcareous soils as stocks for grafting.

**Nut culture, F. M. BARTRAM** (*New England Florist, 3 (1898), No. 49, pp. 547, 548*).—Extracts from a paper given before the Massachusetts Horticultural Society.

**Chestnut culture for fruit, W. A. BUCKHOUT** (*Pennsylvania Sta. Rpt. 1896, pp. 111-121, pls. 2*).—A reprint of Bulletin 36 of the station (E. S. R., 8, p. 497).

**Ornamental asters, H. DAUTHENAY** (*Rev. Hort., 70 (1898), No. 2, pp. 30-33, figs. 10*).—Notes and illustrations of a number of species and varieties.

**Some flowering cherries** (*Garden, 53 (1898), No. 1367, p. 81, figs. 4*).

**Directions for the culture of large-flowered chrysanthemums, V. VIVIAND-MOREL** (*Paris: Doin, 2. ed., pp. 48*).—In this edition a chapter on hybridizing chrysanthemums has been added.

**Hymenocallis and pancratium** (*Garden, 53 (1898), No. 1366, pp. 57, 58, fig. 1*).—Descriptive notes on a number of species of these plants.

**Notes on irises, W. SAUNDERS** (*Canada Expt. Farms Rpts. 1896, pp. 67-69, figs. 5*).

**The Italian, or orchid-flowering, cannas, F. A. WAUGH** (*Vermont Sta. Rpt. 1896-97, pp. 119-122, figs. 3*).—A discussion of the origin of these cannas, with a note on their behavior at the station.

**Culture of Phyllocactus** (*Monatsschr. Kaktcenkunde, 8 (1898), No. 1, pp. 2-5*).

## FORESTRY.

**The timber pines of the southern United States, C. MOHR** (*U. S. Dept. Agr., Division of Forestry Bul. 13, pp. 176, pls. 20, figs. 12*).—This is a revised edition of this bulletin (E. S. R., 8, p. 602), and contains, in addition to changes in the text, notes by F. Roth which supplement the previous studies on the southern pines. In addition a short sketch is given by the same author on the pond pine (*Pinus serotina*). This pine, which, when young, is not easily distinguished from the Loblolly pine, is in some places cut and sold indiscriminately with it, and furnishes from 10 to 15 per cent of the lumber known in the market as North Carolina pine. The growing scarcity of the long-leaved pine has resulted in bleeding this pine for turpentine, the yield of which is fair both in quantity and quality. When its ready reproduction, rapid growth, and ability to occupy poorly drained and otherwise almost

worthless land are considered, the pond pine deserves consideration in all future forest operations in its region.

**Forest trees**, A. MACKAY (*Canada Expt. Farms Rpts. 1896*, pp. 413-416).—A report is given on the present condition of the shrubs and trees in the arboretum, and also the cost of planting and taking care of trees for the first and second years. In 1895 7 half-acre plats were planted with trees at different distances apart for the purpose of ascertaining the cost of planting and keeping them clean and in a thriving condition until the trees had grown sufficiently to need no further cultivation. In 4 plats box elders were planted, in 2 plats green ash, and in 1 plat box-elder seed was sown in rows. The rows were separated 2½, 3, and 3½ ft. The cost of planting and cultivating is shown in tables, in which it appears that the expense of planting and taking care of trees the first and second years varies from \$9.58 to \$12 per acre.

**The United States Forest Reserves**, C. D. WALCOTT (*Pop. Sci. Mo., 52 (1898), No. 4, p. 456*).—Discusses the general features of forest reserves and gives their present extent and location.

**The forest department of the Biltmore Estate, North Carolina** (*Forester, 4 (1898), No. 2, pp. 37-39*).—Describes the Biltmore and Pisgah forests.

**The twenty-fifth annual meeting of the German Foresters** (*Forstw. Centbl., 20 (1898), No. 2, pp. 82-96*).—An account is given of the meeting held at Stuttgart, August 30-September 3, 1897.

**Forestry in Roumania** (*Ztschr. Forst u. Jagdw., 30 (1898), No. 1, pp. 33-43*).

**The native forest trees of Nebraska**, C. E. BESSEY (*Nebraska State Bd. Hort. Rpt. 1897, pp. 3-38*).—The 67 trees indigenous to the State are listed and their range indicated. The most of the species have entered the State from the southeast along the valley of the Missouri River, only a few having come down from the high mountains to the west.

**Forest trees in Nebraska**, P. YOUNGERS (*Nebraska State Bd. Hort. Rpt. 1897, pp. 9-22*).—The general conditions of forestry and some of the difficulties of forest tree culture are given. Notes are also given of the species of trees best adapted to the soils and climate of the State.

**What has the timber-claim law done for Nebraska?** E. F. STEPHENS (*Nebraska State Bd. Hort. Rpt. 1897, pp. 51, 52*).—The author states that about 4,000,000 acres were taken up under that law and more than 500,000,000 trees were planted. The beneficial effects of this planting are shown and the statement made that these plantings were spreading.

**Partial abstract of timber cut during the year 1896 in Pennsylvania**, J. T. ROTHROCK (*Pennsylvania Dept. Agr. Rpt. 1896, pp. 407-409*).—The report shows that there were 140,150 acres of woodland cut over, yielding 1,330,425,908 ft. of timber, board measure, and 486,389 cords of bark.

**Forest value of trees as determined by timber tests**, H. MAYR (*Forstw. Centbl., 20 (1898), No. 2, pp. 72-82*).

**Losses by forest fires in Pennsylvania during 1896**, J. T. ROTHROCK (*Pennsylvania Dept. Agr. Rpt. 1896, pp. 416, 417*).—From partial reports the author estimates the actual money value of timber destroyed by fires at \$557,056.

**Forest destruction and stream flow in southern California**, A. KINNEY (*Forester, 4 (1898), No. 2, pp. 41, 42*).—Notes the destruction caused by the rapid running off of water from the Soledad watershed after the forest growth had been destroyed.

**Relation of forests to the farmer**, J. T. ROTHROCK (*Pennsylvania Dept. Agr. Rpt.*

1896, pp. 382-396).—Discusses the origin and value of forests, their importance, and how they may be restored.

**Forestry for farmers**, B. E. FERNOW (*U. S. Dept. Agr., Farmers' Bul.* 67, pp. 48, figs. 15).—This is a reprint from the Yearbooks of this Department for 1894 and 1895 (*E. S. R.*, 7, p. 508; 8, p. 794).

**Care of woodlands**, W. H. BUCKHOUT (*Pennsylvania Sta. Rpt.* 1896, pp. 122, 123).—Notes are given on the care of oak woodlands by which they may be made more productive.

**Forest conservation**, A. J. BOYD (*Queensland Agr. Jour.*, 1 (1897), No. 6, pp. 478-482).

**Sheep grazing in forest reserves**, F. V. COVILLE (*Forester*, 4 (1898), No. 2, pp. 30-32).

**American oaks in Campine** (*Bul. Soc. Cent. Forst. Belg.*, 5 (1898), No. 1, pp. 45-60).—Notes are given on *Quercus rubra*, *Q. palustris*, *Q. tinctoria*, *Q. coccinea*, *Q. phellos*, and *Q. imbricaria*.

**Culture of pines in the Main-Rhine Valley** (*Forstw. Centbl.*, 20 (1898), No. 2, pp. 66-72).

**On the growth of the buds of *Pinus sylvestris***, E. BERGER (*Bul. Soc. Cent. Forst. Belg.*, 5 (1898), No. 1, pp. 26-36).

**On the collection of forest tree seed**, E. PARISEL (*Bul. Soc. Cent. Forst. Belg.*, 5 (1898), No. 1, pp. 13-26).

**On the effect of lime rings on the health of fir trees**, A. CIESLAR (*Centbl. Gesam. Forstw. Wien*, 24 (1898), No. 1, pp. 21-34, figs. 8).

**Structure and weight of the best coniferous timber**, R. HARTIG (*Forstl. Naturw. Ztschr.*, 7 (1898), No. 1, pp. 1-19).

**Conifers of the Pacific coast**, J. G. LEMMON (*Sierra Club Bul.*, 2 (1898), No. 3, pp. 156-173, pls. 3).

**Evergreens—their use and value**, E. H. RICKER (*Nebraska State Bd. Hort. Rpt.* 1897, pp. 56-61, figs. 8).—Notes are given on the value of different evergreens for forest planting, together with directions for their propagation.

**Ash of *Gidgea acacia* (stinking wattle)**, F. B. GUTHRIE (*Agr. Gaz. New South Wales*, 8 (1897), No. 12, pp. 868, 869).—An analysis of the ash of *Gidgea acacia* is reported; also a partial analysis of the leaf.

## SEEDS—WEEDS.

**Preliminary report on the artificial use of enzymes in germination**, F. A. WAUGH (*Vermont Sta. Rpt.* 1896-97, pp. 106-111, figs. 2).—The author reports upon a series of experiments conducted with various unorganized ferments to ascertain their effect on the germination of various seeds. The enzymes used were pepsin, diastase, extractum pancreatis, trypsin, enzymol, and diastatic essence of pancreas, using them in different strengths of solution. Among several hundred preliminary experiments, many gave negative results and frequently the effect of the enzym solution was detrimental. The temperature at which the treatment and germination are made is of great importance, and it seems probable that the particular enzym combination must be separately determined for each species of seed. The author has tabulated the results of his experiments with tomato, cucumber, radish, and watermelon seeds ranging from 5 to 12 years old. The seed were soaked in different solutions from 24 hours to 1 week before planting, and the percentages of germination are compared.

The following table gives the percentages of germination of seed soaked in different enzym solutions, 50 or 100 seeds being used in every case:

*Germination of seed soaked in enzym solutions.*

Kind of seed.	Age.	Time of soaking.	Water.	Pepsin (5 per cent).	Diastase (5 per cent)	Diastase and pepsin.	Extract pancreatis.	Trypsin.	Enzymol.	Diastatic essence of pancreas.
	Years.	Hours.	Per ct.	Per ct.	Per ct.	Per ct.	Per ct.	Per ct.	Per ct.	Per ct.

<sup>1</sup> Where two figures are given, the first indicates double strength of solution.

The following tentative generalizations are given:

"In some cases the percentage of germination in seeds is greatly increased by soaking for several hours in a solution containing some active enzym or enzymes.

"The vigor of the young plantlets is often enhanced at the same time.

"Within limits these beneficial effects increase with the strength of the enzym solution.

"Diastase, either from malt or from various commercial preparations, seems to be most useful.

"Tomato seeds seem to respond especially well to the action of enzymes, particularly to the action of diastase."

**Weeds and seeds, F. L. HARVEY** (*Maine Sta. Rpt. 1896, pp. 113-116*).—Several causes for the distribution and spread of weeds are discussed, and the attention of farmers and others is called to the sources of distribution. The author believes that more bad weeds are introduced into the State through grain brought in by the carload for feed than by means of seeds. A lot of oats which had been brought from the West was purchased from a local dealer, who represented it as cleaned seed and charged several cents per bushel above the market price for it. Examination of a pound of this seed showed the presence of 1,160 mustard seed, 576 black bindweed, 111 goosefoot, 13 smartweed and sorrel, 28 flaxseed, 20 grass seed, several foxtail, 4 wild morning glory, 3 bugloss, and several seeds of 6 different kinds of Compositae. Another sample examined (8 oz. of fowl seed screened from oats bought for seed) contained seeds of the following: Black mustard, English charlock, jointed charlock, shepherd's purse, pigweed, bindweed, smartweed, bugloss, flaxseed, morning glory, several

kinds of grass seed and Compositæ, and one seed that looked like Russian thistle.

Samples like the above are said to be not uncommon, and the author recommends that farmers should not import whole grain for feed. Other suggestions are given for the solution of the seed and weed question.

**The vitality of seeds** (*Sci. Amer.*, 78 (1898), No. 8, p. 121).—Reports subjection of seeds to 180° C. without injury to their vitality.

**The vitality of dormant and germinating seeds**, F. ESCOMBE (*Sci. Progress*, n. ser., 1 (1897), No. 5, pp. 585-608).—Gives a review and bibliography of literature relating to this subject.

**Two weeds**, J. T. ROTHROCK (*Pennsylvania Dept. Agr. Rpt. 1896*, pp. 414-416, pl. 1).—Brief notes are given of the blue thistle (*Echium vulgare*) and the yellow daisy (*Rudbeckia hirta*).

**Noxious weeds**, J. FLETCHER (*Canada Expt. Farms Rpts. 1896*, pp. 275, 276, fig. 1).—A brief note is made on the cow cockle (*Saponaria vaccaria*), known also under the different names of cow herb, china cockle, and soapwort. "This plant has been noticed as an aggressive enemy in field crops only during the last 2 years, and so far only in the province of Manitoba, where it has spread very rapidly." The indications are that it was introduced from Europe in flaxseed.

**The orange hawkweed**, L. R. JONES (*Vermont Sta. Rpt. 1896-97*, pp. 62-74, figs. 5).—This is an abridgment of Bulletin 56 of the station (E. S. R., 8, p. 987).

**Notes on plants**, F. L. HARVEY (*Maine Sta. Rpt. 1896*, pp. 109-112).—Brief notes are given on various plants that were sent to the station for identification. Many of these were weeds, and methods for their destruction are suggested.

**On the destruction of weeds with iron sulphate**, DELARCHARLONNY (*Jour. Soc. Agr. Brabant-Hainaut, 1897*, No. 49).

## DISEASES OF PLANTS.

**Report of the botanist**, L. R. JONES (*Vermont Sta. Rpt. 1896-97*, pp. 44-62).—The results of the investigations on potato diseases, orchard diseases, oat smut, and onion mildew, and their remedies, are given. The conditions during the season of 1896 were rather unfavorable for the development of the fungi causing the diseases of potatoes. There was no occurrence of the late blight fungus at the station, but the other diseases of the potato occurred much as in the previous year.<sup>1</sup>

Studies of the fungi associated with the early blight were made, and an extensive bibliography of *Alternaria solani* is given. The synonymy of the fungus is also given.

Tests of various forms of Bordeaux mixture were made, in which a standard Bordeaux mixture, another containing one-half as much lime, and a Bordeaux powder were compared. Comparing the rows where the Bordeaux powder and the solutions were used showed conclusively that the Bordeaux powder is practically worthless as a fungicide. The results secured indicate that standard Bordeaux mixture (copper sulphate 1½ lbs., lime 1 lb., water 10 gal.) and the mixture containing half as much lime gave almost identical results, and there is practically no

<sup>1</sup> Vermont Sta. Rpt. 1895, p. 78 (E. S. R., 8, p. 992).

choice between them. The solution of Bordeaux mixture when one-half the quantity of lime was used did not color the plants as much as the standard mixture, and on this account might be preferred where ornamental plants are sprayed or where there is danger of staining fruit.

The effect of disinfectants upon the growth of seed potatoes was tested, the seed being soaked  $1\frac{1}{2}$  hours in a 1:1,000 solution of corrosive sublimate. The seed tubers were soaked in this solution on the day of planting, and 46 and 96 days before planting. Comparisons were made with seed potatoes treated with formalin solution. The general conclusions drawn are that disinfecting with corrosive sublimate just before planting retards the early growth of plants, while if performed  $1\frac{1}{2}$  to 3 months before planting there is no such effect noticed. The use of formalin seemed to exert no retarding effect, but is said to have slightly stimulated the growth.

Brief notes are given on the diseases of apples observed during 1896. The most serious of these troubles is called the apple scald, and seemed most widely spread on Greenings. These apples, which appeared perfectly sound at the time of harvest, became discolored at various periods during the winter, a light brownish tinge appearing in fairly well-defined spots, which became more or less diffused over the surface. This light color passes to a dark-brown shade, and usually terminates in a black rot. Associated with the black rot is usually a fungus, but this is a secondary affair, the primary discoloration being due to a breaking down of the tissues of the fruit. Various theories are given relative to the conditions which may cause these diseases, the consensus of which is that the fruit had not attained perfect maturity at the time of storing. The author discusses the relation of conditions in the storeroom to the development of the scald, and shows that temperature and ventilation are important factors in its development.

The observations on oat smut were continued from the previous year, and the percentage of smut on the different varieties and plats for 1895-96 are tabulated. The effect of the Jensen hot-water treatment on the yield of oats was tested, and where perfectly clean untreated seed was used there was no gain, and there may have been a decrease in the yield due to the hot-water treatment.

The studies on onion mildew reported previously in the report of this station for 1895, p. 113 (E. S. R., 8, p. 994), were continued and the conclusions reaffirmed. Field experiments were made with fungicides to test their efficiency in preventing the onion mildew, but the solutions did not adhere well to the leaves, and the Bordeaux mixture proved quite injurious on account of its too great strength. No mildew appeared in this field on any of the plats, consequently the fungicidal values were undetermined.

**The cause of a brown rot in cruciferous plants, E. F. SMITH** (*Centbl. Bakt. u. Par., 2. Abt., 3 (1897), Nos. 11-12, pp. 284-291; 15-16, pp. 408-415; 17-18, pp. 478-486, pl. 1*).—The author has made a study

of a microorganism which is the cause of the bacteriosis of ruta-baga, described by L. H. Pammel.<sup>1</sup>

The author's attention was first called to the diseases on turnips which were brown rotted internally and usually hollow, the cavities presenting a more or less radial structure. He succeeded in isolating a yellow rod-shaped motile organism, which agreed in most particulars with that described by Pammel. Soon after diseased cabbages were received from Racine, Wisconsin, which were attacked by a microorganism, and the disease bore such a striking resemblance to that on the turnips as to suggest their possible identity. A series of experiments was conducted, which showed that the two diseases were due to the same germ and that they could be produced by cross inoculation. Further study showed that quite a number of cruciferous plants were capable of having this disease induced in their tissue through artificial inoculation.

One of the most striking symptoms of the disease is a brown or black staining of the tissues occupied by bacteria and, so far as the author's experience goes, the decay induced is that of a sort of dry rot. The disease is peculiarly a vascular one, and the rapid distribution of the bacteria is due to the fact of their motility. Various methods of natural infection were investigated and it was found that the disease could be spread in the greenhouse by slugs and various leaf-eating insects. The water pores at the margins of the leaves were also found to be avenues for infection. The author believes it probable that a majority of the natural infections in the field take place above ground, the disease being transmitted to healthy plants as the result of visits of insects or other small animals, and also that the disease may be transmitted from field to field by the way of the manure pile. He suggests as preventive measures (1) that susceptible plants should not be cultivated on land subject to this disease, (2) the prompt removal of diseased plants, and (3) the destruction of insect enemies and other possible carriers of the disease.

In the concluding portion of this paper the organism is described, its appearance on beef bouillon, cabbage broth, gelatin, agar, potato, and other media given, and its action in fermentation tubes and its thermal relations stated.

According to the system of bacteriological nomenclature adopted by the author, the organism was not properly referred by the original discoverer and it has been given the name *Pseudomonas campestris*. It is described as follows:

"A yellow, rod-shaped, motile microorganism. Size and color varying according to substratum, food supply, etc. Generally 0.7 to 3.0 by 0.4 to 0.5  $\mu$ . One polar flagellum. Nonsporiferous, so far as known. Pathogenic for various cruciferous plants, entering and dwarfing or destroying the host plant through the vascular system, which becomes decidedly brown. Aerobic but, so far as known, not a gas

---

<sup>1</sup>Iowa Sta. Bul. 27 (E. S. R., 6, p. 998).

or acid producer, *i. e.*, not facultative anaerobic. Forms cavities around the bundles, but seems to be only feebly destructive to cellulose. Produces a brown pigment in the host plants and on steamed cruciferous substrata, especially the turnip. Grows very rapidly on steamed potato cylinders at room temperatures but without odor or the formation of any brown pigment. Liquefies gelatin. Grows well at 17 to 26° C., and is killed by 10 minutes' exposure to 51° C. Organism closely related to Wakker's *Bacterium hyacinthi*, from which it differs chiefly in its pathogenic properties, its duller yellow color, and its higher thermal death point."

**The black rot of the cabbage**, E. F. SMITH (*U. S. Dept. Agr., Farmers' Bul. 68, pp. 22, fig. 1*).—The author gives a popular bulletin on the black rot of cabbage, which is of bacterial origin, due to *Pseudomonas campestris*. Technical descriptions of this disease have been previously given.<sup>1</sup> The disease in cabbage is characterized by the dwarfing or one-sided growth of heads or, if the disease is very severe and began early in the season, by the entire absence of heads and, in extreme cases, by the death of the plant. If the stumps of affected plants are broken or cut across, a brown or black ring will be observed corresponding to the woody part of the stem, this being the part of the plant subject to disease.

The cause of the disease, as has already been stated, is bacterial, the germ entering the plant above ground and usually at the margin of the leaves through the water pores. It is not confined to cabbage, but attacks a number of other plants belonging to the mustard family. The common charlock or wild mustard is very subject to the disease and may be the means of causing its spread.

An account is given of field studies made in 1897, together with its geographical distribution. At present it is known to occur in Alabama, Kentucky, Iowa, Nebraska, Illinois, Indiana, Ohio, Minnesota, Wisconsin, Michigan, New York, Pennsylvania, New Jersey, Maryland, Virginia, and possibly Florida. The different methods of introduction and transmission are discussed, as well as the susceptibility of different varieties. Indications seem to show that the parasite lives over winter in the soil.

Suggestions for the prevention of disease are given, the principal of which briefly summarized are to plant the cabbage seed in a seed bed where the disease has never occurred and set plants on land which has not been in cabbage or other cruciferous plants for some years. As a matter of precaution, the use of stable manures should be avoided, since they may possibly serve as a means of conveying the germs to uninfected fields. Infection must be guarded against from tools used on infected lands or allowing stock to pasture over the different fields. The cabbage butterfly and harlequin cabbage bug must be constantly kept in subjection, as it is probable that they are very efficient means in spreading the disease. As a palliative remedy all diseased plants should be removed as quickly as they appear, and weeds, especially

<sup>1</sup> Iowa Sta. Bul. 27 (E. S. R., 6, p. 998); Centbl. Bakt. u. Par., 2. Abt., 3 (1897), No. 11-12, p. 284 (see above).

wild mustard, which harbors the disease, must be destroyed. If the cabbage is stored in the fall, all heads showing any trace of black in the stem should be rejected and the others stored in a house in all parts of which the temperature is kept below 40° F. If any affected heads are stored they should be kept by themselves in a separate part of the house.

**A bacterial disease of celery,** U. BRIZI (*Centbl. Bakt. u. Par.*, 2, *Abt.*, 3 (1897), *No.* 21-22, pp. 575-579).—A report is given of a bacterial disease of celery which was observed during the past season at several places in the lower part of the valley of the Po River, Italy. The bases of the large petioles of the leaves, especially when covered with earth, become discolored, while the remaining green portions of the leaves are spotted with small yellow specks which finally change to a rusty red. With the appearance of the spots the tissues become diseased and broken down and at the same time ulcer-like patches appear with great rapidity, destroying the tissue of the leaf. Finally there are formed large reddish areas surrounded by a definite line, the whole extending through the leaf.

Examinations of the ulcers revealed the presence of innumerable bacteria about 2 to  $2\frac{1}{2}$   $\mu$  in length, to which the provisional name *Bacterium apii* has been given. The organism is attenuated at its extremities, motile, and fully occupies the tissues where found, often appearing in the collenchyma and in the tissues immediately surrounding the vascular bundles.

The organism is readily grown upon a variety of media. On gelatin it grew best at temperatures of from 20 to 22° C., colonies appearing in 18 to 24 hours and assuming their characteristic appearances in from 5 to 6 days. Its growth on different media and action toward various staining reagents are fully described.

Attention is called to the bacterial disease of celery described by Halsted<sup>1</sup> and a disease mentioned by Russell some time later. The identity of this disease in Italy with those occurring in the United States is not affirmed nor denied, the author merely claiming the first description of the Italian disease.

**The core rot of apples and pears,** J. CRAIG (*Canada Expt. Farms Rpts.* 1896, pp. 172, 173, fig. 1).—A brief note is given on a core rot of apples and pears to which the Gideon apple and Bessemianka and Sapieganka pears, 2 Russian varieties, are particularly subject. The core of the apple, which is at first water-cored, becomes brown and shrunken, separates the carpels from the surrounding pulp, and remains suspended in the interior of the fruit. Varieties that are affected by this disease should be avoided, or, if grown, the fruit should not be kept late in the winter, as its value will be lost.

**A dry rot of apples,** J. CRAIG (*Canada Expt. Farms Rpts.* 1896, pp. 171, 172, fig. 1).—Notes are given on the occurrence of a peculiar dry rot of apples which has been observed for several years. The dis-

<sup>1</sup>New Jersey State Sta. Bul. Q (E. S. R., 3, p. 885.)

ease is externally manifest by circular depressions on the surface of the apple. On removing the skin each depression is found to be the center of a small area of dryish brown tissue. The affected flesh is dry and without flavor, but not bitter. Some varieties seem to be more severely attacked than others, and, while the fruit is not wholly unfit for use, its appearance and salability are greatly affected. The disease is compared with several other of the better known diseases of apples, and is thought to be distinct from them. The specific cause of the disease is in some doubt, it having been attributed to a species of *Dothidea*, while others consider it a fruiting form of *Fusicladium dendriticum*. The life history of the disease is a subject for further investigation.

**Apple and pear blight**, J. CRAIG (*Canada Expt. Farms Rpts. 1896*, pp. 168-171).—Brief notes are given descriptive of the apple and pear blight, together with suggested remedies, which consist in removing diseased branches and spraying with Bordeaux mixture. The spraying alone has been tried without success. A tabulated report is given on the resistance to blight of about 140 varieties of Russian apples in an orchard at Ottawa. The record covers the years 1893 to 1895, inclusive, and shows a considerable variation in the resistant power with the different varieties, and the same variety in different seasons.

**Spraying**, J. CRAIG (*Canada Expt. Farms Rpts. 1896*, pp. 173-175, fig. 1).—A report is given on experiments conducted with various combinations of fungicides and insecticides with a view to preventing the cracking of pears and injury by the late brood of codling moth. The fruit of both sprayed and unsprayed trees was uniformly free from fungus attacks and no results were gained in this respect. The spraying mixtures used were solutions of arsenate of lead, lysol, copper carbonate, and Paris green. The fruit of one Bartlett tree of each series which had been sprayed twice with each mixture was picked and graded, and it was found that the tree sprayed with lysol gave the largest percentage of sound fruit.

These experiments gave results somewhat contrary to those of the previous year, especially in respect to the use of arsenate of lead, and are to be repeated. Notes are also given on the injury to apples by spraying with Bordeaux mixture, and directions are given for its prevention.

**The fungus foes of the farmer**, B. D. HALSTED (*Pennsylvania Dept. Agr. Bul. 28*, pp. 19, figs. 6).—Brief popular notes are given of the more common and destructive diseases of farm crops, root crops, vegetables, and orchard and small fruits.

**Three years' experience with club root**, B. D. HALSTED (*Amer. Gard., 19* (1898), No. 162, p. 74, fig. 1).

**Potato scab**, SCHELLENBERGER (*Fühling's Landw. Ztg., 46* (1897), No. 22, p. 651).

**Diseases of the Irish potato**, R. H. PRICE (*Texas Sta. Bul. 42*, pp. 923-926, figs. 4).—Brief popular notes are given describing the early blight (*Macrosporium solani*), late blight (*Phytophthora infestans*), potato scab (*Oöspora scabies*), and dry rot (*Fusarium solani*). Directions are given for their prevention.

**The rusts of cereals**, D. PINOLINI (*La ruggine dei cereali. Novara, 1897*, pp. 20).

Notes on spraying, W. M. MUNSON (*Maine Sta. Rpt. 1896, pp. 162-165*).—Reprint of Bulletin 29 of the station (E. S. R., 8, p. 240).

## ENTOMOLOGY.

Some little-known insects affecting stored vegetable products, F. H. CHITTENDEN (*U. S. Dept. Agr., Division of Entomology Bul. 8, n. ser., pp. 45, figs. 10*).—This is a collection of articles detailing certain original observations made upon insects of this class.

A storehouse moth new to the United States, with notes on other species (pp. 7-10).—The dried currant moth (*Ephestia cahiritella*) was obtained both at the World's Columbian and the Cotton States Expositions and

was brought prominently to the author's attention in material collected at Atlanta. It was found in nearly every exhibit of chocolate nuts or cacao beans. The moth looks much like *Ephestia kuehniella* and also *E. clutella*, but it may be distinguished from the former by the strong subdorsal line of the cilia of the hind wings. The larva resembles that of the flour moth, exhibiting the same color variation, the green hues ranging from dirty whitish to gray or yellowish. The flesh tints are arranged along the dorsum so as to form with the piliferous warts (which are darker than in *E. kuehniella*), a distinctly striated appearance not present in the latter species. The larvæ were found in a lot of flaxseed meal from Calla, Ohio, and in English walnuts, figs, and pearl hominy obtained from various markets and street venders. A larva was found in a small box of duplicate moths to which it had wrought much damage.

*Ephestia clutella*, the chocolate moth, is also noted as a new American pest. It has been found breeding in cayenne pepper at Iowa City, Iowa, in dried apples from New York, and in cacao beans from Montserrat, West Indies; and, according to various European authorities, in manufactured chocolate, coffee, various dried fruits, and ship biscuit.

The storehouse moths liable to introduction are *Ephestia ficulella*, which preys upon figs and currants and has been found in oatmeal; *E. calidella*, which feeds on dried figs, raisins, and currants; *Ephestia* (?) sp., an unknown phycitid larva resembling *Ephestia*, which has been found in pressed figs in Washington; and *Myelois ceratonia*, found in a box of seed pods of St. John's bread (*Ceratonia siliqua*) exhibited by the Spanish Colonies at the Columbian Exposition. Another moth noted is *Corecra cephalonica*, which occurs in dried currants in Europe.

*Notes on grain beetles of the genus Silvanus* (pp. 10-13).—Under this head the author considers *Silvanus bicornis*, *S. mercator*, and *S. gossypii*, n. sp. The distinctive features of each are pointed out. The second form was found at the Columbian Exposition in material from Venezuela, Vienna, and Italy, and at the Atlanta Exposition in material from Venezuela. It has also been found in a lot of ground flaxseed from Calla, Ohio. *S. gossypii* was found in cotton seed from India. It has not yet been introduced into this country.

*Granivorous and other habits of certain Dermestidæ* (pp. 14-24).—According to recent observations, at least 4 common species, namely, *Attagenus piceus*, *Trogoderma tarsale*, *T. sternale*, and *Anthrenus verbasci*, have vegetarian proclivities. The larvæ of *Attagenus piceus* have been found in wheat and flour from central Indiana, in middlings, corn meal, in pumpkin seeds, and in millet at Washington. After a few notes on the injury of insects to bolting cloth—injuries which have been incorrectly attributed to *Tenebroides mauritanicus*—the author reviews briefly the history of the species in America and then briefly describes it.

*Trogoderma tarsale* has been found in flaxseed, peanut-oil cake and dust, Indian turnips, wheat, corn, "kulu," cayenne pepper, and in beehives. They were found breeding in cayenne pepper.

*Trogoderma sternale* has been found in sample seeds, in linseed, castor beans, silkworm cocoons, and in red-clover seed. In the jars of cocoons it was found associated with *Trogoderma tarsale* and a few individuals of *Attugenus piceus*.

*Anthrenus verbasci* (pp. 22, 23).—To the two instances<sup>1</sup> in which this species has been noted as attacking vegetable substances the author adds that the species has been found in middlings, in spoiled flour, in peanuts, and in meal, flour, and cakes prepared from them, and from peanut-oil cake, in seed wheat, and in cayenne pepper. Experiments showed that they will make themselves at home in fresh flour. The change from the natural animal-feeding habit to a vegetable one is attributed to altered environments.

Weevils that affect the seed of the cowpea (pp. 24–29).—The author here considers *Bruchus chinensis* and *B. quadrinaculatus*, which he compares, and in both cases notes the records of damages, distribution, and development, and, in the case of *B. chinensis*, the natural enemies.

Development of the common bean weevil (pp. 29, 30).—From the author's studies of this insect (*Bruchus obtectus*), it appears that the egg stage lasts from 5 to 20, the larval stage from 11 to 42, the pupal stage from 5 to 18, and the entire life cycle from 21 to 80 days. The development is much affected by temperature.

A little-known grain weevil (*Caulophilus latinasus*) (pp. 30, 31).—This insect was collected at the Atlanta Exposition, where it was found living in Indian corn, Spanish peas, or chick peas, from Mexico. This case appears to be the only recorded instance of its occurrence in either stored cereals or legumes, but it has been found at Kingston, Jamaica, in ginger.

On the occurrence of the grain moth (*Tinea granella*) in America (pp. 31–35).—This wolf, or little grain moth, of Europe, is noted as occurring rarely in this country. The fact is pointed out that *Plodia interpunctella* affects grain in much the same manner. It is thought very likely that many of the leading cases of damage attributed to *T. granella* are due in reality to *Plodia interpunctella*. According to recent reports, *T. granella* has been found in stored wheat from California and bred from larvæ taken from a sack of corn meal from San José. It has been found by 7 station entomologists in as many States. The species likely to be confused with *T. granella* are *T. pali*, *T. spp.*, *T. (Scardia) cloacella*, and *T. defectella*. Of the unnamed species one was found in breeding *T. pali*, the other in breeding *T. cloacella*. *T. pali* was found in Yucca pods from Mexico. The question of the presence in America of *T. granella* is thought to rest upon rather insecure footing. The cases recorded are supposed to be instances of accidental introduction.

An invasion of the coffee bean weevil (pp. 36–38).—Specimens of this weevil (*Araverus fusciculatus*) were found in dried apples in Washington. They had been introduced in Java coffee. The beetle is figured and described. The species is also noted as feeding on seed pods of

<sup>1</sup> Insect Life, 7, p. 32; Field and Forest, 2 (1877), p. 184.

the so-called coffee weed or senna (*Cassia occidentalis* and *C. obtusifolia*), the seeds of the wild indigo of Florida (possibly either *Indigofera tinctoria* or *I. anil*), on dried orange from Florida, in cacao beans from Liberia, and in mace from Trinidad and Jehore.

*Parasites of flour and meal moths* (p. 38).—Notes are given on the parasites in the following list, in which the names of the parasites follow the name of the host: *Ephestia kuehniella*—*Hadrobracon hebetor* (syn. *Bracon brericornis*), *Apanteles ephestia*, *Chremylus rubiginosus*; *E. elutella*—*Hadrobracon hebetor*; *E. cahiritella*—*Hadrobracon hebetor*, *Omorga frumentaria*; *Plodia interpunctella*—*Hadrobracon hebetor*, *Omorga frumentaria*, *Limneria ephestia*; *Pyralis farinalis*—*Apanteles carpatus*, *Perilitus ictericus*, *Erochus mansuetor*, unknown ichneumonid, *Spalangia rugicollis* (secondary), *Melanophora roralis*, *Clausicella tarsalis*, *Carcelia leucania*; *Tinea granella*—*Chremylus rubiginosus*, *Omorga frumentaria*, *Hemiteles tineæ*; and *Galleria mellonella*—*Hadrobracon hebetor*.

*A foreign parasite of the grain weevils* (pp. 43–45).—The author discusses the only hymenopterous parasite known to infest the grain weevils in the United States, namely, *Pteromalus calandra*, which is now referred to the genus *Meraporus*. The author considers it an introduced cosmopolite. Some remarks are made on the taxonomy, and the insect is described.

**Report of the entomologist and botanist, J. FLETCHER** (*Canada Expt. Farms Rpts. 1896, pp. 226–276, pl. 1, figs. 18*).—Accounts are given of insects affecting cereals, fodder crops, fruits, etc., and apiary experiments.

*Cereals* (pp. 226–229).—The following insects are noted: Hessian fly (*Cecidomyia destructor*); the jointworm (*Isosoma hordei*); grain plant louse (*Siphonophora avenæ*); amputating brocade moth (*Hadena arctica*), which was very abundant in some parts of Ontario during 1895, and gave considerable annoyance by soiling clothes and curtains and by dying in large numbers in shop windows; in the same districts during 1896, wheat, oats, and corn were destroyed; pea moth (*Semasia* sp.), which is again attracting attention by the extent of its injuries; the wheat stem sawfly (*Cephus pygmaeus*), of which a summary of the life history is given; and the army worm (*Leucania unipuncta*).

*Fodder crops* (pp. 234–243).—The insects noted as attacking fodder crops are the clover root borer (*Hylesinus trifolii*), white grubs (*Lachnosterna*), cottony grass scale (*Eriopeltis festuæ*), grasshoppers (*Melanoplus femur-rubrum*, *M. bivittatus*, and *M. atlantis*), the parasites (*Empusa grylli*), tachina flies, hair worms, *Trombidium locustarum*, the gray blister beetle) of which are noted.

In discussing hair worms (Gordius, etc.), it is noted that 2 small specimens of *Mermis* were taken from a ladybird (*Hippodamia 13-punctata*).

It is reported that on Sable Island locusts were so destructive that it was necessary to purchase hay to keep stock through the winter.

*Root crops and vegetables* (pp. 243-250).—Few complaints were received, but the following insects are noted: Turnip flea beetle (*Phyllotreta vittata*), red turnip beetle (*Entomoseclis adonidis*), which did considerable damage in the Northwest Territories and in Manitoba; striped cucumber beetle (*Diabrotica vittata*), clover cutworm (*Mamestra trifolii*), zebra caterpillar (*Mamestra picta*), which was abundant in the western parts of Ontario, but was much affected by the parasites *Trichogramma pretiosa* and *Telonomus* sp., and by *Apanteles*; small white cabbage butterfly (*Pieris rapæ*), which affected turnips as well as cabbages injuriously; Colorado potato beetle (*Doryphora 10-lineata*), and red backed cutworm (*Carneades ochrogaster*).

*Fruits* (pp. 250-264).—There are noted the codling moth (*Carpocapsa pomonella*) eye spotted bud moth (*Tmetocera ocellana*), cankerworms, cigar case bearer (*Coleophora fletcherella*), oyster shell bark louse (*Mytilaspis pomorum*), pear tree slug (*Eriocampa cerasi*), plum webworm (*Lyda rufipes*), San José scale (*Aspidiotus perniciosus*), which was discovered in Vancouver Island, where the pest must have existed on the trees affected for some time; plum curculio (*Conotrachelus nenuphar*), grape phylloxera (*Phylloxera vastatrix*), peach bark borer (*Phænotribus liminaris*), black peach aphid (*Aphis persicæ-niger*), apple maggot, and apple fruit miner, which has become a serious enemy to the apple growers on the Pacific Coast, where it attacks the apple at about the same time and in much the same way that the apple maggot does in the East. The apple fruit miner is abundant in the wild crab, and its habit of attacking apples seems acquired and exceptional, but persistent. Appended to the foregoing is a note on the horn fly (*Hæmatobia serrata*).

*Experiments in wintering bees, J. Fixter* (pp. 264-271).—During 1895, 1896, and 1897 experiments begun in former years were continued. The most satisfactory way of wintering in a cellar was found from these experiments to be the following: Hives are placed in the cellar, raised from the floor by empty hives or other means, and arranged in tiers with the back of the hive raised somewhat higher than the front, and each hive raised from its bottom board by a small block  $\frac{3}{4}$  in. high. All front entrances are left wide open so as to give free ventilation. The wooden covers of the hives are replaced by chaff cushions 4 in. thick, above which are placed strips of wood to prevent their coming in contact with the hives above. In hives packed with sawdust, preventing ventilation, bees were smothered, and in hives similarly treated, but with ventilation, the colonies were weakened by heat, dampness, and insufficient ventilation. Hives packed with chaff and left out of doors on the ground without ventilation, or with none other than the ventilating shaft, were found to have been sufficiently protected, but in the former case to have suffered considerably from water which found its way into the hive.

Notes are also given on buckwheat, 5-banded Italian bees, a hive in

a wood shed, the daily gain in honey of a hive, a bee cellar, and wintering experiments in 1896 and 1897; and a few suggestions are made to beginners in apiculture.

A swarm of bees taken June 13, weighing  $6\frac{3}{4}$  lbs., furnished with 4 frames of drawn comb and 4 frames of foundation placed alternately, and kept on scales for 11 weeks from June 17, made a total net gain of  $90\frac{3}{4}$  lbs., the largest gain of any one day being  $6\frac{1}{4}$  lbs. This gain was made on two days, one during clover and the other during basswood flow. There is noted also a loss of  $7\frac{1}{2}$  lbs., which is the sum of losses noted in 4 different weeks and which the author apparently attributes to the differences connected with the weight of brood, etc.

*Report upon further experiments with certain brands of comb foundation, F. T. Shutt* (pp. 271-275).—The experiments of former years were continued. The results of this year's work apparently show, taking the values of comb foundation as depending upon the extent to which it is used by bees in cell formation, that what the author designates choice wax made on the Root mill at a temperature of  $89^{\circ}$  F. gives the best results, while the foundation made by a patent process and running 12 or 15 sq. ft. to the pound gives the poorest results. In the former case the average percentage of the wax of the foundation utilized by the bees was 52, as contrasted with 12 in the latter case. A poor quality of wax in any of the foundation used seems to give bad results. In obtaining percentages noted the method was followed of paring off the cells of the comb and comparing the weight of the piece thus obtained with that of the foundation when placed in the hive.

**Report of the entomologist, A. D. HOPKINS** (*West Virginia Sta. Rpt. 1893, pp. 29-18*).—After stating that the common insect pests were not sufficiently numerous during the year to attract serious attention, the pine bark beetle is noted as occasioning great damage during 1891-'93. "Never before in the history of the country has such widespread and universal destruction of timber been caused by the ravages of insects." Extensive travel through the spruce and pine forests of the State showed that the death of the trees was due to the attack of *Dendroctonus frontalis*. As the result of a circular letter mailed to various timber owners, setting forth the dangerous character of the attack, some \$750 was contributed, to which the station added \$150, for the purpose of carrying on investigations and to import predacious insects from Germany. After a number of weeks of study in Europe *Clerus formicarius* was chosen from a number of beneficial predacious insects for importation. As a beginning 50 specimens, male and female, and 25 larvæ were placed on dying trees near Morgantown. During the following spring and summer (1893) colonies of often as many as from 30 to 100 each were placed throughout the State. In all, including insects from a second importation, 14 distributions were thus made. The number of the pests were so decimated by disease, etc., as not to threaten any material damage in the future.

There is also noted a study of a new potato disease, due to the larvæ of a dipterous insect; and a new peach tree pest, the peach twig moth (*Anarsia lineatella*).

**Annual report of the entomologist, A. D. HOPKINS** (*West Virginia Sta. Rpt. 1895, pp. 27-35*).—During the year attention was given to an insect affecting chestnut, oak, and pine bark, which in some instances did considerable damage. Among the discoveries made during the year was an adult of the chestnut timber worm, which proved to be an insect entirely different from what either Harris or Riley had supposed. *Xyletinus peltatus* was found doing damage to pine barn flooring, and it was further noted as a dangerous enemy to seasoned wood of all kinds, especially in outbuildings. Other insects noted are an enemy of the poplar, a new apple tree pest, a new enemy of plum trees, which is probably an imported European pest, the bagworm, clover leaf mite, and an oyster shell bark louse. A new form of potato scab is also noted.

**Notes on the insects of the year, F. L. HARVEY** (*Maine Sta. Rpt. 1896, pp. 117-123, figs. 7*).—The following insects are noted: Croton bug (*Phyllostromia germanica*), oyster shell bark louse (*Mytilaspis pomorum*), which is abundant and increasing; hemispherical scale (*Lecanium hemisphaericum*), elm tree bark louse (*Lecanium* (?)), the fall cankerworm (*Anisopteryx pomotaria*), mourning cloak butterfly (*Vanessa antiopa*), oak bark weevil (*Magdalis olyra*), steel blue flea beetle (*Haltica chalybea*), buffalo tree hopper (*Ceresa bubalus*), which was this year reported for the first time as doing damage to apple trees; yellow necked apple tree caterpillar (*Datana ministra*), reported this year for the first time as feeding on the foliage of apple trees; the currant spanworm (*Diastictis ribearia*), very abundant about Orono; gooseberry fruit worm (*Dakruma courotutella*), which is apparently on the increase; lime tree winter moth (*Hybernia tillaria*), which is reported in injurious numbers and seems to remain where the fall cankerworm is about to disappear; the army worm (*Leucania unipuncta*), the ash gray pinion (*Lithophana antennata*), velleda lappet moth (*Tolyte velleda*), which has never been found before in Maine and was received from the western part of the State, where it was mistaken for the gypsy moth; apple tree tent caterpillar (*Clisiocampa americana*), which is very abundant in western and southern Maine; currant fly (*Epochra canadensis*), which is not generally distributed, but badly infested some gardens in Orono; apple maggot (*Trypeta pomonella*), which has nearly disappeared in several localities; rat tail larva (*Mollota*), horn fly (*Hematobia serrata*), which seems to be on the decrease; buffalo beetle (*Anthrenus scrophulariæ*), pigeon tremex (*Tremex columba*), and *Ptinus fir*, which was reported as badly infesting a bag of timothy seed. The great number of leaf-eating insects said to have been reported makes the season somewhat remarkable.

**The army worm, B. H. WARREN** (*Pennsylvania Sta. Rpt. 1896, pp. 161-220, pls. 16*).—A description is given of the moth, its eggs and

larva, its life history, and its past history. The subject of parasites, predaceous insects, etc., is very briefly treated. Ditching and the use of coal tar or kerosene in the ditches is the only remedy recommended. A long series of letters is given which were received in reply to a circular sent out over the State. The most prominent feature of this is the estimate of loss, which foots up about \$300,000. The greatest loss noted by a single individual is \$400. One is reported at \$300 and several at \$200. Among the damages done by the worm there is noted a destruction of the uniformity of a lawn by their producing a ragged appearance along the edges of the walks. Swallows, fly catchers, crows, blackbirds, robins, catbirds, thrushes, meadow larks, bluebirds, sandpipers, the screech owl, sparrow hawk, and the skunk are mentioned, each more or less at length, as enemies of the worm. The plates are all colored.

**The red spider**, G. H. PERKINS (*Vermont Sta. Rpt. 1896-'97*, pp. 75-86, figs. 1).—An account is given of the life history of the red spider (*Tetranychus telarius*) taken partly from notes made by J. H. Worcester. These so-called spiders vary in color more or less according to the food plant upon which they are found and according to their age. On some plants red mites may be very numerous, on others there will be found few red, but many greenish or brownish ones. When young they are light yellowish or whitish. Somewhat later 2 red spots appear on each side of the back. These spots may be all the red that is developed, or the color may spread and increase in depth with age so that the spots become completely obliterated. Very fine webs are spun.

The eggs, which are relatively large, spherical, and light yellow or colorless, are laid at intervals of a few days, the female remaining in one spot the while. In about a week, according to conditions of temperature, etc., an oval six-legged mite hatches out and 2 days later sheds its skin, grows, and repeats the process twice at intervals of 2 days. Immediately after the third molt, if males happen to be present, the female is impregnated by one or more and within 48 hours begins laying. From 2 to 8 eggs per day are deposited for as many as 3 weeks, producing during that time a total of 50 to 100 eggs. One impregnation suffices for a lifetime. If no males chance to be present the female proceeds to lay unfertilized eggs, which hatch out males. This may go on until the female is impregnated, after which a majority of female eggs may be produced. The mites show a very friendly and peaceable disposition. The males seldom quarrel, even over the possession of a female. Occasionally, however, the males apparently fight, darting at one another and apparently endeavoring to pull away one another's tongues, which are thrust out and withdrawn.

Under the head of remedies, the statement, based upon what seem to be conclusive experiments, is made that the mites are not so injuriously affected by excessive humidity of the atmosphere as to render the method of saturating the atmosphere with water vapor, as is often done in greenhouses, of practical value. But the mechanical action of

water spurted on the plants, as has been recommended by the author for aphids, mealy bugs, and the like, is fairly effective, as also are soap emulsions. Sulphur fumes in some cases have proved satisfactory, but none of these remedies seem effectual against the eggs. Kerosene emulsion, however, is effective in all cases and will, it is thought, be found the most convenient and satisfactory remedy.

**A new garden Smynthurid (*Smynthurus albamaculata*), F. L. HARVEY** (*Maine Sta. Rpt. 1896, pp. 121-126, figs. 5*).—A detailed description is given of a new Smynthurid which the author calls *Smynthurus albamaculata*. It is found abundantly in gardens during May and June and does considerable damage to early garden plants, attacking radishes, beans, cucumbers, squashes, etc., in the leaves of which it eats numerous holes and sucks away the juices until the leaves wither. The habits are thus the same as *S. hortensis* of Fitch. The species is, however, readily distinguished from the latter species by the purple of the head, antennae, terminal segments of the body and elater, and by the obscure white marking of the body, and especially by the 9 instead of 6 segments in the terminal portion of the antenna.

The young are much lighter in color than the adults and often show only 8 segments in the terminal portion of the antenna.

Under the head of remedies the author states that he can not agree with Fitch that the work of the smynthurids is entirely secondary, for this species, at least, seems capable of sucking the juices of plants without the aid of other insects. This species was very abundant on cucumbers in his garden, but there was no evidence of the flea beetle. Some dozen or more would sometimes be found on a single leaf and in a few days it would be noticed that the leaves turned whitish, and an examination of the epidermis would show the existence in it of numerous little pits. A hole through the leaf was rarely if ever found. The new leaves, cotyledons, etc., are attacked. Dirt, ashes, sulphur, or pyrethrum will act as deterrents until the plants are large enough to be out of danger.

**A bacillus pathogenic upon the phylloxera and certain acarids, L. DUBOIS** (*Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 20, pp. 790, 791*).—In a mixture of earth and manure the author found an organism that in certain hemiptera produces a veritable infectious disease. Apparently it enters the body through the mouth and may be found either by means of the microscope or by cultures in the bodies of insects that have succumbed to the disease. In certain solutions it seems capable of retaining its virulence for a very long time.

It exists in 2 forms: In filaments of 4 to 7  $\mu$  somewhat undulating in form, in links and as a coccus from 0.2 to 0.3  $\mu$  in diameter. The coccus is slightly motile and has an annular zone, usually distinguished as a somber tint surrounding a central rather clear area. There is no vacuole. In some cultures the cocci seem to develop from spores.

The organisms stain with difficulty by ordinary methods. The best results were obtained by the author with 10 cc. of a 25 per cent solution

of tannin to which was added enough sulphate of iron to give the mixture a black color. The mixture was heated to 50° C. and then left on the cover glass for 25 minutes. The cover glass without washing was then plunged into a solution of 1 per cent potassium hydrate for 5 minutes. It was then washed in water and stained by the aid of heat with a soda anilin solution of fuchsine and finally stood in water. The stain thus obtained is instable and works with difficulty on cocci forms and on old cultures. The organism is an aerobic, at least with ordinary media. It develops well only in the absence of oxygen, but the growth is never luxuriant. The temperature limits are between 20 and 30°. Its virulence seems to vary with the chemical constitution of the soil and with atmospheric conditions.

In 12 lots of phylloxera experiments 2 lots were placed in the ground as control experiments, 8 were placed in earth in potatoes and sown with the organism, and 2 were placed on a lot of blotting paper. In 1 or 2 days the insects on the twigs of the last 2 lots were all dead. At the end of 5 days few living insects were found in the 8 lots, while in the control experiment plenty of them were found after the lapse of 7 days.

**Report of the entomologist, L. BRUNER** (*Nebraska State Bd. Agr. Rpt. 1896*, pp. 105-138, figs. 35).—This consists of notes, descriptive and otherwise, on the common or injurious grasshoppers of Nebraska, with observations as to remedies. The latter portion of the paper is formed by a list of the short-horned grasshoppers occurring in the State.

**Contributions to experimental entomology, E. FISCHER** (*Illus. Ztschr. Ent.*, 2 (1897), No. 44, pp. 689-695, pl. 1).—Experiments in which *Faenusa antiopa*, *V. aberratio artemis*, and *V. aberratio hygiara* were subjected to cold are described.

**Species or subspecies, T. D. A. COCKERELL** (*Nature*, 56, No. 1452, p. 391).

**Revision of the European and related species of the Ichneumonid genus Pimpla, O. SCHMIEDEKNECHT** (*Illus. Wechschr. Ent.*, 2 (1897), Nos. 32, pp. 506-511; 33, pp. 525-528; 34, pp. 539-543; 36, pp. 571-576; 37, pp. 589-591; 39, pp. 618-622; 40, pp. 633-638).

**The braconid genus Meteorus, O. SCHMIEDEKNECHT** (*Illus. Wechschr. Ent.*, 2 (1897), Nos. 10, pp. 150-154, figs. 5; 11, pp. 173-175; 12, pp. 184-190; 13, pp. 204-207; 14, pp. 221-223; 19, pp. 298-302).

**Diptera from the white sands on the Tularosa plains of southern New Mexico, I. C. H. T. TOWNSEND** (*Psyche*, 8 (1897), No. 259, pp. 138-140).—*Paragus bicolor testaceus*, *P. tibialis*, and *Zodion fulvifrons abdominale* all on flowers of *Aster parviflorus*.

**Diptera of the Organ Mountains in southern New Mexico, I. C. H. T. TOWNSEND** (*Psyche*, 8 (1897), No. 258, pp. 126-128).—A brief description is given of the following, with the altitudes at which they were caught: *Eupeodes volucris*, 5,000 ft., on flowers of *Melampodium cinereum*; *Zodion splendens*, 5,000 ft., on *Zinnia grandiflora*; *Zodion fulvifrons*, 5,500 ft., on *Pectis papposa*; *Belrosia bifasciata*, 5,600 ft.

**The Coleoptera of the lower Rio Grande Valley, H. F. WICKHAM** (*Bul. Lab. Nat. Hist. State Univ. Iowa*, 4 (1897), No. 2, pp. 96-115).—Species of Cicindelidae, Caribidae, Haliplidae, and Hydrophilidae are noted. Only a score of specimens peculiar to Mexico were obtained, and these were found in a cotton field near Matamoros.

**Winter case arrangement for bees, P. S. ORTON** (*Amer. Bee Jour.*, 37 (1897), No. 20, p. 305).—A winter case costing about \$3.50 and holding 10 two-story, 8-frame, dove-tailed hives is described. It is 13 ft. long, 2½ ft. wide, and 2½ ft. deep. The hives

stand 1 in. apart; the entrance is  $\frac{7}{16}$  by 12 in. next a space in the case of  $1\frac{1}{2}$  by 2 by 14 in. A block 1 by  $1\frac{1}{2}$  by 2 in. is placed between each hive and the entrance to the strip  $\frac{1}{2}$  by 2 in. by 13 ft. is nailed to the top of these blocks, thus forming 10 compartments of  $1\frac{1}{2}$  by 2 by 14 in. The roof is of the gable sort and furnished with a loek. The floor of the porticos slants so that dead bees and the rain fall away.

**A nonswarming device** (*Amer. Bee Jour.*, 37 (1897), No. 16, p. 241, fig. 1).—It is stated that bees desiring to swarm may be controlled by placing two hives side by side, each having a 6-inch tin tube inserted in a hole bored in the lower side of the middle of the front. When the entrance of one hive is closed the workers are obliged to come out through the tin tube and, being unable to get back, go into the adjoining hive. After several days the entrance to the second hive may be closed and that of the first one opened, which forces the bees back into the first hive again. The method is said in no way to interfere seriously with the working of the bees, but it effectually destroys the swarming fever and all queen cells that may have been formed are torn down.

**The San José scale in Missouri**, J. M. STEDMAN (*Missouri Sta. Circ. Inf.* 3, pp. 10, figs. 2).—A brief popular account of the scale, with a recommendation of the usual precautions and remedies.

**A report on the occurrence of the cabbage root maggot**, F. A. WAUGH (*Vermont Sta. Rpt.* 1896-'97, pp. 116-119, figs. 1).—It is briefly noted that cabbage, cauliflower, broccoli, and kale were found attacked by this insect (*Phorbia brassicæ*). There are a few comments on its distribution, method of feeding, life history, and treatment. The use of kerosene emulsion about the roots of the affected plants is recommended, as is also the preventive measure of placing tarred paper about the stem of the plant at transplanting time, and especially that of avoiding planting in ground where the insect has been at work the year before.

**A further communication relative to the grapevine beetle**, K. SAJÓ (*Illus. Wchuschr. Ent.*, 2 (1897), No. 9, pp. 129-134).—The question as to whether *Eumolpus obscurus* has been found on the vine is discussed and affirmative evidence brought forth. Topsent's hypothesis that *E. vitis* and *E. obscurus* are one and the same, and that the difference in color is due to the food plant from which each may chance to be taken, is shown to be without the support of facts or even an investigation.

**The beech woolly louse**, C. SCHROEDER (*Illus. Wchuschr. Ent.*, 2 (1897), No. 15, pp. 225-229, fig. 1).—*Schizoneura lanigera* is discussed. A wash of 50 parts soap, 100 parts amylic alcohol, 200 of alcohol, and 650 of soft water is recommended.

**Life histories of the New York slug caterpillars, X-XI**, H. G. DYAR (*Jour. New York Ent. Soc.*, 5 (1897), No. 2, pp. 57-65, pls. 2).—*Euclea delphiniæ* (with the food plants—oak, chestnut, bayberry, Andromeda, beech, sour gum, and wild cherry) and *Parasa chloris* (food plants—oak, chestnut, wild cherry, hickory, and bayberry).

**The willow leaf beetles**, RÖRIG (*Illus. Ztschr. Ent.*, 2 (1897), No. 42, pp. 657-661).—More or less of the life history of *Chrysomela vulgatissima*, *Phratora vitellina*, *P. cornulense*, and *Gabruca caprea* is discussed.

**Injurious insects**, A. ACLOQUE (*Paris: Felix Alcan*, p. 192, figs. 67; rev. in *Zool. Centbl.*, 4 (1897) No. 26, p. 917).

**The egg sacs and larvæ of some grasshoppers (Acridiidae)** J. INGENITZKY (*St. Petersburg*, 1896, pp. 8, ill.; rev. in *Zool. Centbl.*, 4 (1897), No. 26, pp. 917, 918).—The egg sacs of some West Siberian Acridiidae affecting grains.

**The injurious animals of our cultivated plants, III** (*Deut. Landw. Presse*, 24 (1897), No. 59, p. 540).—Short notes on several Lepidoptera.

**The small lepidopterous genus Lithocollitis, II**, C. SCHROEDER (*Illus. Ztschr. Ent.*, 2 (1897), No. 40, pp. 625-629, figs. 7).

**The distribution of Lepidoptera**, PREUX (*Illus. Wchuschr. Ent.*, 2 (1897), No. 20, pp. 305-309; 21, pp. 332-334, maps 3).

**A little-known birch enemy**, SCHENKING-PRÉVÔT (*Illus. Ztschr. Ent.*, 2 (1897), No. 42, pp. 661-664, pl. 1).—*Incurraria tumorigica*. The eggs of this moth are laid at the axils of the leaves or where a new twig is starting—one at a place. The larva

lives in the adjacent tissue, producing a swelling so that affected twigs have a knotted appearance. The moth is somewhat rare and was first noted by Amerling at Prag.

**A new grapevine disinfectant**, B. H. RIDGELY (*U. S. Consular Rpts.*, 1898, No. 209, pp. 267-269).—A brief note is given of a new compound called phylloxerol, used in Switzerland with good effect against the phylloxera. It has the double effect of destroying the insects and of acting as a fertilizer. It may be applied to other plants as well as to the vine. In the case of the vine a small hole is scooped out around the vine and in it 8.3 to 12.5 ozs. of the phylloxerol placed and the earth filled in again. This operation is repeated in the spring. According to the manufacturer<sup>1</sup> about 55 lbs. of the substance is sufficient for 1 acre of vines for 2 or 3 years.

**Destruction of locusts**, L. BERGHOLZ (*U. S. Consular Rpts.*, 1898, No. 209, pp. 269, 270).—The destruction of locusts by arsenic poisoning in Natal is noted. The poison consists of arsenite of soda made by dissolving 1 lb. caustic soda in 4 gal. of boiling water and adding 1 lb. of arsenic. To this 8 gal. of hot or cold water, and 20 lbs. of brown sugar are added; or by mixing it with 10 gal. of treacle. Bunches of corn, grass, etc., dipped in the mixture are placed along the roads where the locusts can get them.

## FOODS—ANIMAL PRODUCTION.

**Report of preliminary investigations on the metabolism of nitrogen and carbon in the human organism**, W. O. ATWATER, C. D. WOODS, and F. G. BENEDICT (*U. S. Dept. Agr., Office of Experiment Stations Bul.* 41, pp. 61, figs. 1).—These investigations were made at Wesleyan University, Middletown, Connecticut, by the Connecticut Storrs Station in coöperation with this Department. They have been briefly reported in previous publications.<sup>2</sup> The object was to determine the income and outgo of matter and energy. The balance of matter is expressed in terms of nitrogen and carbon. The determination of the balance of hydrogen was also attempted, but the results obtained and the measurements of the heat given off by the body are not reported. Proximate and elementary analyses were made of the food, urine, and feces, and their fuel value was determined with a bomb calorimeter. The respiratory products were measured and analyzed, the amount of carbon dioxid and water being determined. In connection with the experiments, the apparatus used was modified and improved and experimental methods were elaborated. For the measurement of the respiratory products and energy of the body a respiration calorimeter of special construction was devised.

The inside dimensions of the respiration chamber are 2.15 by 1.22 by 1.92 meters, and the volume approximately 4.8 cubic meters. The chamber consists of 3 concentric boxes, the inner one of metal and the two outer ones of wood. The inner box, or chamber, is double walled, the inner wall being of sheet copper, the outer of sheet zinc. The 2 walls are 8 cm. apart. An opening in the front end of the metal

<sup>1</sup>Eugene Courvoisier (Versoix, Canton of Geneva, Switzerland).

<sup>2</sup>Science, 5 (1897), No. 117, pp. 493-496 (E. S. R., 8, p. 821); Connecticut Storrs Sta. Rpt. 1896, p. 85.

chamber serves both the purpose of a window and a door for entrance and exit.

A current of air is pumped through the apparatus and measured by special devices. Samples of the incoming and outgoing air are taken for analysis.

An inconvenient rise of temperature is prevented by a current of cold water which passes through a system of pipes inside of the chamber. This device forms a part of the arrangements for measuring the heat given off from the body.

It is desirable to have the incoming current of air as dry as possible. To reduce the water content to a minimum the air which came from out of doors was dried before it entered the chamber by surrounding a portion of the pipe through which it passed with a freezing mixture of salt and ice. The amount of water remaining in the incoming air and that in the outgoing air was determined by passing the sample through U tubes filled with pumice stone saturated with concentrated sulphuric acid. The carbon dioxide in the samples of air was determined by passing the air through tubes filled with soda lime. A U tube, containing glass beads drenched with barium hydroxid solution, was also used as a control.

A full description of the different parts of the apparatus is given, and the methods followed in conducting a metabolism experiment are described in detail.

The subjects of the experiments were a laboratory janitor, a chemist, and a physicist, all young men in good health. The food consisted of a simple mixed diet, which in every case was selected in accordance with the dietary habits of the subject. Two tests were made with the laboratory janitor. In each the subject remained in the respiration chamber  $2\frac{1}{3}$  days, although the digestibility of the food was determined for a longer period ( $4\frac{2}{3}$  days). In the experiment with the chemist the subject remained in the respiration chamber 5 days, and the digestion experiment, which covered several days before the subject entered the respiration chamber, was of  $8\frac{1}{3}$  days' duration. In these tests the subjects performed no muscular work, and spent their time in reading or resting.

The experiment with the physicist was of longer duration than the preceding, the subject remaining in the respiration chamber 12 days. The digestibility of the food was determined on several days before the subject entered the chamber and during the experiment, making  $16\frac{2}{3}$  days in all. The respiration experiment was divided into 5 periods. The first and fifth periods were of  $1\frac{1}{2}$  and  $1\frac{3}{4}$  days' duration, respectively, and were regarded as preliminary and supplementary. The subject avoided both muscular and mental work as much as possible. The remaining periods were each of 3 days' duration. The second was devoted to severe mental labor; the third was spent in absolute rest, the subject avoiding as far as possible all mental and physical

exercise; and the fourth was a period of quite severe muscular activity. The subject spent 3 hours each day in raising and lowering a 5.7 kg. iron weight by means of a pulley.

The income and outgo of nitrogen and carbon and the fuel value of the food, urine, and feces are recorded in full for each of the experimental periods. In the following table the results for the balance of income and outgo of nitrogen and carbon are summarized:

*Income and outgo of nitrogen and carbon.*

	Nitrogen.				Carbon.				
	In food.	In urine.	In feces.	Gain (+) or loss (-).	In food	In urine.	In feces.	In respiratory products.	Gain (+) or loss (-).
	Gms.	Gms.	Gms.	Gms.	Gms.	Gms.	Gms.	Gms.	Gms.
Laboratory janitor: Rest (2 days).....	45.4	39.2	1.8	+ 4.4	578.6	22.7	18.0	428.2	+ 109.7
Do.....	38.4	36.1	3.2	- 0.9	521.2	28.6	19.8	435.1	+ 37.7
Chemist: Light mental work (5 days).....	76.5	68.7	4.5	+ 3.3	171.5	54.6	34.5	1,099.6	- 17.2
Physicist:									
Rest (1½ days).....	26.3	23.2	2.3	+ 0.8	396.7	13.5	17.1	276.2	- 10.1
Mental work (3 days).....	48.6	39.4	4.2	5.0	732.3	26.3	31.5	696.6	- 22.1
Rest (3 days).....	48.6	37.4	4.2	7.0	732.3	32.2	31.5	713.2	- 44.6
Muscular work (3 days).....	48.6	42.4	4.2	2.0	732.3	30.1	31.5	1,114.6	- 443.9
Rest (1½ days).....	22.3	21.5	1.9	- 1.1	335.6	17.2	14.4	336.6	- 32.6
Whole experiment (12 days).....	194.4	163.9	16.8	13.7	2,929.2	119.3	126.0	3,237.2	- 555.3

From the income and outgo of nitrogen and carbon the gain or loss of protein and fat was calculated.

"The experience here obtained emphasizes the desirability of longer experimental periods than have been customary in experiments of this class. Although a considerable number of respiration experiments have been made with animals and man, the periods have rarely exceeded 24 hours.

"The prospects for obtaining a satisfactory balance of income and outgo of energy are, on the whole, decidedly encouraging. The determinations of heats of combustion by the bomb calorimeter are eminently satisfactory, and there seems to be good ground to hope that ultimately the measurements of heat given off from the body may also prove sufficiently accurate for such purposes. . . . Experience in this laboratory since the above experiments were made have yielded results agreeing very closely, indeed, with the theoretical figures.

"The results of these experiments and of similar investigations elsewhere bring out very clearly the difference in the amounts of nutrients and energy required by the organisms of different persons under different conditions, and confirm the results of previous inquiry in showing that muscular labor is performed at the expense of the fats, sugars, and starches. They also make it clear that the body may draw upon protein for this purpose, although it has not yet been determined just what are the conditions under which this is done."

**The chemistry of the corn plant, F. T. SHUTT** (*Canada Expt. Farms Rpts. 1896, pp. 208-211*).—Analyses are reported of a number of varieties of corn (whole plant) in the following stages of growth: Tasseling, silking, early milk, late milk, and glazing. The amounts of the different constituents per ton and per acre furnished at the different periods of

growth are also computed. Using the ordinarily accepted coefficients of digestibility, the author computed the digestible matter per ton and per acre as follows:

*Digestible matter in corn fodder at different stages of growth.*

Stage of growth.	Digestible matter in one ton.	
	Pounds.	Pounds.
Tasseling .....	186.2	4,220
Silking .....	211.0	5,069
Early milk .....	256.5	5,873
Late milk .....	285.9	6,012
Glazing .....	339.2	7,308

Among the conclusions reached were the following: "Cutting the corn before it reaches the glazing condition—a practice quite common a few years ago—is not to be advised, since in the later stages of the plant's growth there is a large gain in food constituents. . . . The mineral constituents (ash) are taken by the plant from the soil more particularly during its early stages of growth." As the plant matures the amount of nonalbuminoid nitrogen decreases while the albuminoid nitrogen increases. The percentage of carbohydrates also increases as the plant approaches maturity.

**Analyses of fodders and feeding stuffs** (*Maine Sta. Rpt. 1896, pp. 28, 29*).—Analyses are reported of the following feeding stuffs: Sunflower (heads and whole plant); English horse beans; silage from mature corn, sunflower heads, and horse beans; corn planted at 6, 9, and 12 inches; King gluten meal; potato pomace, and black grass (*Juncus gerardi*). The composition of a number of these is given in the following table:

*Analyses of feeding stuffs.*

	Water.	Protein.	Fat.	Nitro- gen-free extract.	Crude fiber.	Ash.
	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.	Per cent.
Sunflower heads .....	86.07	1.93	1.49	5.62	3.79	1.10
Sunflower, whole plant .....	85.21	1.70	1.03	6.14	4.00	1.92
English horse beans .....	82.65	3.88	.49	7.18	3.71	2.09
Silage—mature corn, sunflower heads, and horse beans (average of 4 analyses) ..	69.69	3.97	1.88	16.71	6.13	1.62
Potato pomace .....	10.96	6.56	.52	68.99	10.26	2.71

**Sunflowers and English horse beans as silage crops**, J. M. BARTLETT (*Maine Sta. Rpt. 1896, pp. 32-34*).—For several seasons sunflowers and horse beans have been grown at the station for silage. The crops were harvested in the early part of September, run through a silage cutter, and mixed with corn in the silo in the following proportion: One-fourth acre of sunflowers, one-half acre of horse beans, and one acre of corn. In half the silage the whole sunflower plant was cut up and in half the heads only. Both mixtures were well preserved, and when opened in January were greedily eaten by cows. Although

the stalks of the sunflowers were large and coarse, the silage was eaten as readily as that made from corn alone. The cost of growing the sunflowers and horse beans was estimated to be about the same as that of corn. Analyses of these plants are given above. The yields follow:

*Yield per acre of sunflowers and English horse beans.*

	Weight as harvested.	Weight of dry matter.
	<i>Pounds.</i>	<i>Pounds.</i>
Sunflower heads .....	27,040	3,767
Sunflower, whole plant.....	48,800	7,219
English horse bean, whole plant.....	20,160	3,497

Though the sunflower is a prolific crop, the chemical composition is about the same as that of southern corn grown in Maine. The author does not regard it as a desirable fodder plant when corn can be successfully grown, on account of the coarse, rough stalks and leaves, which render the plant somewhat unpalatable. It would doubtless be largely rejected by stock unless it were ensiled. The fact is pointed out that ensiling prevents the waste of the coarse material which is ordinarily thrown away.

Horse bean was found a satisfactory feeding stuff, though at present prices the author believes it to be more economical to raise the needed corn for coarse fodder and to purchase the concentrated feeds necessary for making up the ration.

**The feeding value of broken hop vines**, F. T. SHUTT (*Canada Expt. Farms Rpts. 1896, p. 216*).—Analysis of hop vines showed the following composition: Water 8.69 per cent, protein 2.53 per cent, fat 0.7 per cent, carbohydrates 33.31 per cent, fiber 50.16 per cent, and ash 4.61 per cent. The sample analyzed is described as being exceedingly woody. In the author's opinion hop vines are inferior to straw as a feeding stuff. Unless well soaked and fermentation induced, the sharp fragments would probably prove injurious. On account of their fertilizing value it is recommended that hop vines be composted, or, if they are too woody for this treatment, that they be burned for their ashes.

**Lacteo-vituline (calf meal)**, F. T. SHUTT (*Canada Expt. Farms Rpts. 1896, pp. 214-216*).—Lacteo-vituline is a feeding stuff prepared in France, and recommended for calves as a substitute for milk. It was found to contain 9.87 per cent water, 16 per cent protein, 8.38 per cent fat, 61.68 per cent carbohydrates, 1.17 per cent fiber, and 2.90 per cent ash, chiefly phosphates, chlorids, and silicates (of calcium, sodium, and potassium). This feeding stuff is compared with cows' milk. The fact is pointed out that it is  $2\frac{1}{2}$  times as costly.

**Relative digestibility of cheat and clover**, G. W. SHAW and H. T. FRENCH (*Oregon Sta. Bul. 47, pp. 8, pl. 1*).—A test was made with a steer to compare the digestibility of cheat and clover. After a preliminary feeding period of 2 weeks the digestion experiment proper began and lasted 6 days. The amounts of food and water consumed are

recorded and analyses are reported of the cheat and clover hay eaten and of the dung. The coefficients of digestibility of the clover hay were as follows: Dry matter 62 per cent, protein 63, ether extract 55, nitrogen-free extract 71, crude fiber 59, and ash 37. The figures for cheat hay were as follows: Dry matter 45 per cent, protein 42, ether extract 32, nitrogen-free extract 49, crude fiber 46, and ash 23.

**The composition of package tea, J. A. WIDTSOE** (*Utah Sta. Rpt. 1897, pp. 31, 32*).—Analyses are reported of 5 samples of tea sold in packages and regarded as typical of that ordinarily sold in the State. The composition of the different samples was as follows:

*Composition of package tea.*

	Water.	Nitrogen.	Thein.	Ash.	Material soluble in water.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Black .....	5.41	4.15	3.38	5.67	51.50
Green, faced.....	6.64	3.63	2.88	6.57	53.48
Do .....	7.97	3.96	3.02	6.76	51.41
Do .....	6.90	4.10	2.18	6.34	55.10
Do .....	5.74	3.83	3.29	6.41	55.79

The black tea was apparently uncolored. The green teas were colored or faced.

**Feeding steers, 1895-'96, W. SAUNDERS** (*Canada Expt. Farms Rpts. 1896, pp. 80-84*).—A test was made with 3 lots of 4 steers each to compare a number of coarse fodders as part of a ration. The test was divided into 3 periods of 6, 8, and 6 weeks, respectively. The feeding experiment proper was preceded by a preliminary period of 6 weeks. The steers were fed the following basal rations per head per day:

Lot 1, 50 lbs. silage, 25 lbs. turnips, 5 lbs. hay.

Lot 2, 25 lbs. corn fodder, 25 lbs. turnips, 5 lbs. hay.

Lot 3, hay and turnips *ad libitum* (about 20 lbs. hay and 50 lbs. turnips).

The silage consisted of corn, horse beans, and sunflower heads in the proportion of 10 : 2½ : 1.

In addition to the basal ration lot 1 was fed per head daily during the second period 2 lbs. of meal and during the third period 4 lbs. of meal, and lots 2 and 3 during the first period 4 lbs. and during the second and third periods 6 lbs. of meal. The meal consisted of equal parts of barley, wheat, peas, bran, and oil cake. The average weight of the steers at the beginning of the test was about 1,000 lbs. The financial statement is based on silage at \$2.50, turnips at \$2, hay at \$8, corn fodder at \$4, and meal at \$20 per ton. The results are reported in detail.

“From these tests it appears that the 4 steers fed on ration 1 gained in all during the feeding period 831 lbs. at a cost of \$6.49 per 100 lbs. The 4 steers fed on ration 2 gained in all during the feeding period 685 lbs. at a cost of \$9.92 per 100 lbs., while the 4 steers fed on ration 3 made a total gain of 693 lbs. at a cost of \$9.83 per 100 lbs.

“Taking the cost per day, each animal in group 1 was fed at a cost of 9.53 cts. per day; group 2, at a cost of 12.18 cts., and group 3, at a cost of 13.53 cts. each per day.

“During the feeding period of 20 weeks, the steers fed on ration 1 gained, on the average, 36½ lbs. per head more and cost 2.65 cts. less per head per day for the feed consumed than the steers which were fed on ration 2; and they gained 34½ lbs. per head more and cost 4 cts. per head less per day than the steers which were fed on ration 3. This appears to show that of the 3 rations used in these experiments, No. 1 was the most profitable.”

**Feeding steers**, S. A. BEDFORD (*Canada Expt. Farms Rpts. 1896, pp. 348, 349*).—A test is reported, made at the experimental farm at Brandon, with 2 lots of 2 steers each, to study the value of turnips as part of a ration. The test continued 147 days. Both lots were fed the same quantities of cut straw and chopped wheat, barley, and oats. One lot was fed turnips in addition. The results are given in tabular form.

In the author's opinion it would appear that at the prevailing prices for grain turnips were fed at a loss. “This, however, is contrary to the general experience of skilled feeders throughout the Dominion, and further and more extensive experiments would be needed before such a conclusion could be accepted.”

**Experiments with cattle**, A. MACKAY (*Canada Expt. Farms Rpts. 1896, pp. 416, 417*).—Tests made at the experimental farm at Indian Head are reported with 5 lots of cattle, to compare a number of coarse fodders. Lot 1 was fed 15 lbs. hay, 5 lbs. straw, 5 lbs. mixed meal, and 20 lbs. turnips; lot 2, 30 lbs. corn silage, 10 lbs. straw, 5 lbs. meal, and 20 lbs. turnips; lot 3, 15 lbs. cut oat sheaves, 20 lbs. corn silage, 5 lbs. meal, and 20 lbs. turnips; lot 4, 20 lbs. corn silage, 8 lbs. hay, 10 lbs. straw, 5 lbs. meal, and 20 lbs. turnips; and lot 5, 15 lbs. cut oat sheaves, 5 lbs. straw, 5 lbs. meal, and 20 lbs. turnips. The meal consisted of wheat screenings and barley.

Lots 1, 2, and 3 were made up of 2 steers each, lot 4 of 2 cows, and lot 5 of a bull and a steer. The first 4 lots were fed for 5 months and the last for 4 months. The total gains made by the different lots were as follows: Lot 1, 555 lbs.; lot 2, 480 lbs.; lot 3, 480 lbs.; lot 4, 447 lbs.; and lot 5, 370 lbs.

**Notes on the cattle show of the Smithfield Club**, G. ROGERS (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 326-331*).—The article contains a record of the live and dressed weights of a number of steers exhibited at the Smithfield Club show, together with the weights of the head, tail, hide, and internal organs. The animals were exhibited alive, and after slaughtering the carcasses were judged for the awarding of prizes. Awards were made on the quality of meat, the proportion of fat to lean in the most valuable parts, the ratio of live weight to dressed weight, and other minor details.

“The deductions that have been made in England from the results of this competition have led to a great amount of discussion on the subject of the profitable fattening of stock. A knowledge of the opinions expressed may be made a source of profit to all who enter to the English trade.

“To appreciate the discussion fully it must first be understood that the typical beef, according to the English taste, consists of a great depth of well-marbled lean flesh. With this fact in mind one can readily see that an inevitable conclusion from

the tabulated results of the competition was that the superabundance of fat, which makes the living animal so attractive to the eye of the breeder, is a certain source of waste and loss to the butcher who buys the animal for slaughter and the profits of English trade."

**Pig feeding, J. L. HILLS** (*Vermont Sta. Rpt. 1896-'97, pp. 31-43*).—In continuation of work previously reported (*E. S. R., 8, p. 1012*) a test was made with 12 pigs to compare the feeding value of corn meal and whole corn and skim milk, and corn meal with whey and wheat bran, and to learn whether skim milk is most profitably fed in large or small quantities. The test was divided into 4 periods of 45, 43, 36, and 62 days each. The pigs were divided into 4 lots of 3 each. Lot 1 was fed 6 qt. of skim milk and 12 oz. of corn meal daily; lot 2 was fed the same quantity of skim milk and 12 oz. of shelled corn; lot 3 was fed 1 oz. of corn meal to a quart of skim milk, the amount being increased to 12 qt. of milk and 24 oz. of corn meal; lot 4 was fed 12 oz. of bran with whey in increasing amounts until 12 qt. was fed daily. During part of the test lots 3 and 4 were fed an additional quantity of corn meal, or corn meal and bran, 1 : 1.

The financial statement is based on skim milk at 15 cts. and whey at 9 cts. per 100 lbs. and corn meal and bran at \$14 and \$12 per ton, respectively. The total cost of the food eaten was \$112.74, leaving as a profit but \$2.55.

The foods consumed and the gains made by each pig are given in tabular form. The pigs were slaughtered and sold for 4½ cts. per pound, dressed weight. The weights and percentage of shrinkage are recorded. The average results of the test are shown in the following table:

*Results of pig feeding.*

	Average weight at beginning of test.	Average live weight at end of test.	Shrinkage in dressed weight.	Dry matter eaten per pound of gain.	Cost of food per pound of increase (dressed weight).	Total profit (+) or loss (—) per pig.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Per cent.</i>	<i>Pounds.</i>	<i>Cents.</i>	
Lot 1 (corn meal and skim milk).....	41	308	14	4.14	4.02	\$1.12
Lot 2 (shelled corn and skim milk).....	41	289	17	4.54	4.42	.24
Lot 3 (corn meal and skim milk).....	45	306	15	4.62	5.17	1.46
Lot 4 (wheat bran and whey).....	40	277	17	4.32	4.09	.81

The author's conclusions are as follows:

"(1) Corn meal proved superior to shelled corn. It is doubtful, however, whether the gain was equal to the extra cost of grinding.

"(2) Whey in large quantities with bran proved a more economical feed than skim milk in large quantities with corn meal, but no more so than skim milk fed in small quantities with corn meal.

"(3) The economy of production was decidedly in favor of small rather than large quantities of skim milk.

"(4) Profits turned to losses as the average pig grew beyond 150 lbs., because of low prices for pork and illiberal feeding during middle life.

"(5) Subtracting the cost of grain from the total receipts, allowing manure to

offset care, skim milk was found to be worth 18 cts. (fed in small quantities), 12 cts. (fed in large quantities), and 15 cts. (average), while whey proved to be worth 11 cts. per hundred.

"(6) The foods contained fertilizing ingredients worth 54 per cent of their cost."

**Experiments in the fattening of swine, W. SAUNDERS** (*Canada Expt. Farms Rpts. 1896, pp. 84-89*).—In continuation of previous work<sup>1</sup> tests were made with 10 lots of 3 to 5 crossbred pigs to compare the value of a number of feeding stuffs. The feeding periods were from 12 to 20 weeks' duration. Sunflower heads and grain were compared with 2 lots, pulped raw potatoes and cooked potatoes with 5 lots, and ground oats and peas and a mixture of the two with 3 lots. In every case skim milk and mixed grain were fed also. The gain in weight made by the different lots and the shrinkage of the carcass on slaughtering are recorded in tabular form.

In the comparison of grain and sunflower heads lot 1, consisting of 5 pigs, was fed for 18 weeks grain *ad libitum* soaked in water for 30 hours and 6 lbs. of skim milk per head daily. Lot 2, consisting of 5 pigs, was fed for the same length of time half as much grain, sunflower heads *ad libitum*, and 6 lbs. of skim milk per head daily. The grain consisted of a mixture of ground barley, rye, wheat, and bran. The following table gives the results of the comparison of sunflower heads and grain:

*Results of feeding sunflower heads and grain to pigs.*

	Weight at beginning.	Weight at close.	Shrinkage in dressed weight.	Food consumed per pound of gain.		
				Milk.	Grain.	Sunflower heads.
	Pounds.	Pounds.	Per cent.	Pounds.	Pounds.	Pounds.
Lot 1 (ground grain and skim milk) . . .	299	932	22.21	4.35	3.10	-----
Lot 2 (ground grain, skim milk, and sunflower heads) . . . . .	305	828	25.60	5.40	1.92	2.11

No general deductions are drawn from the experiments.

**The value of dairy by-products in pig feeding, F. B. LINFIELD** (*Utah Sta. Rpt. 1897, pp. 59, 60*).—A preliminary report is given of a test of the value of skim milk, made with 3 lots of 3 pigs each. Lot 1 was fed skim milk and chopped wheat, 5 : 1, until the pigs averaged 75 lbs., and then in the proportion of 3 : 1; lot 2, skim milk *ad libitum*; and lot 3, chopped wheat mixed with water *ad libitum*. The milk was fed fresh or sour. Lots 1 and 2 received some whey with the skim milk.

The test began January 16 and covered 100 days. The food consumed and the gains made are reported and the value of the foods is discussed, reckoning the gain in weight at 3 cts. and at 4 cts. per pound.

"The gain per day for each hog fed on milk and grain was 2.54 times greater than for those fed on milk alone, and 1.7 times greater than

<sup>1</sup>Canada Expt. Farms Rpts. 1895, p. 191 (E. S. R., 8, p. 921).

those fed on grain alone. The value of the skim milk when fed in combination was 75 per cent greater than when it was fed alone."

**Experiments with swine**, S. A. BEDFORD (*Canada Expt. Farms Rpts.* 1896, p. 350).—A brief report is given of a pig-feeding experiment carried on at the experimental farm at Brandon to compare wheat with mixed grain. Three pigs were fed soaked wheat, and 3 a mixture of ground soaked wheat, barley, and oats, 2 : 1 : 1. The pigs fed wheat weighed 155 lbs. at the beginning of the test, and during 6 months gained 355 lbs., consuming  $4\frac{1}{2}$  lbs. of wheat to a pound of gain. The pigs fed mixed grain weighed 150 lbs. at the beginning and during the 6 months gained 311 lbs., consuming  $5\frac{1}{2}$  lbs. of grain per pound of gain.

In the author's opinion, if the manure be considered an equivalent for the labor of feeding and caring for the pigs and pork be rated at 4 cts. per pound live weight, the wheat would be worth 88 cts. per hundred and the mixed grain 72 cts.

**Investigations on bread for soldiers**, PLAGGE and LEBBIN (*Untersuchungen über das Soldatendrot.* Berlin: A. Hirschwald, 1897, pp. viii, 234).—This volume, which is No. 12 of *Veröffentlichungen aus dem Gebiete des Militär-Sanitätswesens*, contains an investigation of different methods of grinding grain, suggestions for improving bread for soldiers, experiments on milling, digestion experiments (with man) with different kinds of bread, a review of earlier investigations on bread, and a bibliography. In an appendix a considerable number of digestion experiments (with man) with "Aleuronat biscuits" and other similar products are reported.

**Frankfurter sausage, fresh and canned**, G. POPP and C. FRESSENIUS (*Ztschr. Öffentl. Chem.*, 3 (1897), p. 155; *abs. in Vrtljchr. Chem. Nahr. u. Genussmitl.*, 12, No. 2, pp. 155, 156).—The article contains analyses of fresh and canned Frankfurter sausages.

**Fish flesh from a hygienic standpoint**, P. O. SMOLENSKI (*Hyg. Rundschau*, 7 (1897), Nos. 22, pp. 1005-1121; 23, pp. 1166-1180; 24, pp. 1226-1247).—This is a translation by the author of his paper, published first in Russian. The use of fish as food is discussed at length and the results of many investigations are quoted. The article includes a compilation of analyses of fish and fish products, including many from Russian sources, as well as dietaries in which fish formed the sole or principal animal food consumed. A bibliography of the subject is given.

**Canned goods colored with copper**, S. FERENCZI (*Ztschr. Nahr. Untersuch. u. Hyg.*, 11 (1897), No. 21, pp. 346-348).—A discussion of the work of E. Schunck and of Tschirch.

**Composition and value of foods**, J. KÖNIG (*Procentische Zusammensetzung und Nährgehalt der menschlichen Nahrungsmittel.* Berlin: J. Springer, 1897; *rev. in Ztschr. Nahr. Untersuch. u. Hyg.*, 11 (1897), No. 23, pp. 403, 404).—A colored chart showing the composition and digestibility of important foods and the nutrients in dietary standards.

**Composition of Utah feeding stuffs**, J. A. WIDTSOE (*Utah Sta. Rpt.* 1897, pp. 32-34).—Compiled analyses of a number of feeding stuffs made at the station, most of which have been previously published.

**The relative feeding value of certain root crops**, F. T. SHUTT (*Canada Expt. Farms Rpts.* 1896, pp. 211, 212).—Analyses are reported of Pomeranian White Globe, Elephant Purple Top, and Green Top Yellow Aberdeen turnips.

**The practical use of molasses feed**, STRUBE (*Bl. Zuckerrübenbau*, 1897, No. 11, p. 172; *abs. in Centbl. Agr. Chem.*, 26 (1897), No. 12, pp. 805, 806).—Molasses feeds prepared with palm-nut cake and with peat are described and their composition given. From personal observation the author recommends molasses feed for horses, oxen, and cows.

**Dried brewers' grains**, H. P. ARMSBY (*Pennsylvania Sta. Rpt. 1896*, pp. 53, 54).—Analyses are reported of 2 samples of dried brewers' grains. These are compared with analyses reported by the New Jersey Station.

**Oil-cake meal and germ meal**, F. T. SHUTT (*Canada Expt. Farms Rpts. 1896*, pp. 212-214).—Oil-cake meal and germ meal are described and analyses of samples reported.

**Miscellaneous fodder crops**, J. L. HILLS (*Vermont Sta. Rpt. 1896-97*, pp. 188-190).—Analyses are given of red clover rowen, mammoth red clover rowen, alsike clover rowen, white clover rowen, flat pea, vetch and oats, green soy bean, alfalfa, millets, Hungarian grass, Kafir corn, white mustard, endive, and Swiss chard, with remarks upon the value of some of these.

**General observations on oats**, BALLAND (*Jour. Agr. Prat.*, 2 (1897), No. 44, pp. 681, 682).—A discussion of the feeding value of oats. The chemical composition of different crops of oats is given to show how the different constituents vary.

**The composition of preserved egg yolk**, F. JEAN (*Monit. Sci.*, 4. ser., 6 (1897), p. 561; *Ztschr. Analyt. Chem.*, 36 (1897), p. 406; abs. in *Vrtljschr. Chem. Nahr. u. Genussmtl.*, 12, No. 2, p. 162).

**The composition of white of egg**, A. PANORMOFF (*Rev. Internat. Falsif.*, 10 (1897), p. 27; abs. in *Vrtljschr. Chem. Nahr. u. Genussmtl.*, 12, No. 2, p. 162).

**The use of aseptics in food materials**, F. JEAN (*Jour. Hyg.*, 22 (1897), No. 1109, pp. 607, 608; 23 (1898), No. 1011, pp. 10-12).—An address before the Société Française d'Hygiène.

**The preservation of eggs and the production of eggs rich in iron and phosphorus**, L. BERNEGAU (*Pharm. Ztg.*, 42 (1897), p. 381; abs. in *Vrtljschr. Chem. Nahr. u. Genussmtl.*, 12, No. 2, p. 161).

**The curing of meats** (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896*, pp. 97-108).—The process of curing Smithfield hams is described at length as well as the methods followed by a number of packing houses in curing beef, ham, mess pork, dry salted backs, etc.

**Foods, hygiene, and dietary standards**, H. CATHELINEAU and A. LEBRASSEUR (*Des aliments, hygiène, et régimes alimentaires*. Paris: Ruell & Co., 1897; rev. in *Jour. Hyg.*, 22 (1898), No. 1014, p. 48).—In addition to general discussion, this volume contains tables of analyses of a number of foods with dietaries suited to persons of different ages and occupations.

**Dietary studies at the Maine State College** (*Maine Sta. Rpt. 1896*, pp. 128-140).—This is a brief account of work reported in Bulletin 37 of this Office (E. S. R., 9, p. 162).

**On the condition of the protein in resting and working muscles**, D. I. KURAEV (*O Byelkorom Sostoyanii Muishtz Pokoimnikh i Dyejatelunnikh*. Inaug. Diss., St. Petersburg (Russian), 1896, pp. 204).—A large number of experiments were made with isolated muscles of frogs and rabbits. The work is described and discussed in detail. The author believes with Pflüger that there is in the muscles a reserve substance of unknown composition which by its cleavage performs work. This is neither sugar, nor fat, nor ordinary protein, but is living matter. Fat and carbohydrates in one way or another enter into the living protoplasm and thus participate in the production of mechanical work. The rôle of the fats and carbohydrates is very important and perhaps essential. The author's principal deduction is that living tissue of muscle, *i. e.*, the proteid bodies it contains, must necessarily take part in the production of mechanical work.

**The computation of rations for farm animals**, H. P. ARMSBY (*Pennsylvania Sta. Rpt. 1896*, pp. 18-52, pls. 2).—This includes a discussion of the general principles of feeding, computation of rations, and the composition, digestibility, and fertilizing value of a number of feeding stuffs, as well as the percentage composition of the bodies of sheep, steers, and pigs.

**The use of sugar in cattle feeding**, A. PETERMANN (*L'Ing. Agr. Gembloux, 1897, p. 538; abs. in Centbl. Agr. Chem., 27 (1897), No. 1, pp. 43-45*).—The author discusses some of the recent work on feeding molasses and reports analyses of feeding stuffs prepared from extracted beet chips and molasses.

**Fattening calves with skim milk and peanut oil**, MINNA PETERSEN (*Milch Ztg., 26 (1897), No. 25, pp. 397, 398, figs. 3*).—A general article.

**Skim milk and starch for fattening calves**, A. GOUIN (*Milch Ztg., 26 (1897), No. 31, pp. 493, 494*).—A popular article quoted from *Jour. Agr. Prat.*

**Experiments with swine**, A. MACKAY (*Canada Expt. Farms Rpts. 1896, p. 417*).—A test was made at the experimental farm at Indian Head with 2 Yorkshires, 2 Tamworths, and 2 crossbred pigs, to compare the gains made by the different breeds. The ration is not stated. The Yorkshires and Tamworths were about 4 months old at the beginning of the test and the crosses about 3 months old. They were all fed for 111 days. The Yorkshires gained 280 lbs., the Tamworths 315 lbs., and the crossbred pigs 304 lbs.

**Pigs, breeds, and management**, S. SPENCER (*London: Vinton & Co., 1897, pp. 180, pls. 19*).—A general treatise, with a chapter on the diseases of the pig by J. W. Axe and a chapter on bacon and ham curing by L. M. Douglas.

**Poultry**, S. A. BEDFORD (*Canada Expt. Farms Rpts. 1896, p. 351*).—Brief statistics are given of the poultry division of the Brandon experimental farm. The age and weight of the different breeds of poultry and the eggs obtained from each breed are recorded.

**Report of the poultry manager**, A. G. GILBERT (*Canada Expt. Farms Rpts. 1896, pp. 277-295, 415, figs. 7*).—Detailed plans for a poultry house are given. Among other subjects the following are discussed: The proper food and feeding of poultry, shortening the season of nonproduction, and the proper selection of breeding stock. Breeding experiments with a number of different varieties of chickens are briefly reported and statistics given of the laying stock and the number of eggs laid throughout the year. Wild geese were mated with Toulouse crosses. They did not agree and the eggs proved infertile. Brief statistics are also given of the poultry kept and the rations fed at the Indian Head experimental farm.

**Ducks and geese**, G. E. HOWARD (*U. S. Dept. Agr., Farmers' Bul. 64, pp. 48, figs. 37*).—This bulletin discusses standard breeds of ducks and geese and their management.

## DAIRYING—DAIRY FARMING.

**The effect of various preparations of molasses on milk secretion**, RAMM (*Landw.-Jahrb., 26 (1897), No. 1-5, pp. 733-765*).—An experiment is reported at considerable length to study the effect of molasses-peat feed (80 per cent molasses and 20 per cent peat), liquid molasses, molasses, and palm-nut meal, molasses pulp (a dried mixture of potato-pulp residue and molasses), and molasses chips (a dried mixture of molasses and sugar-beet diffusion residue) in comparison with barley meal. A constant ration of hay, straw, and beets was fed. Eight cows were used, and the experiment covered 7 periods, usually of 20 days duration, only the last 5 days of each period being considered in making the averages. The method of making the different molasses preparations is described. The animals were weighed every other day. The yield and fat content of the milk were determined daily, and the sugar content was determined at frequent intervals. Several times in each period the milk of all the cows was churned and made into butter to test the quality. The detailed data for each of the cows are given, and

from these data summaries are made of the averages for each period, the averages calculated to 1,000 kg. live weight, and the averages corrected for the natural decline with advancing lactation.<sup>1</sup>

The results with 2 of the cows were not considered normal, owing to digestive and other disturbances, and these were excluded in making up the averages. The average results for the 6 cows in each period are summarized below:

*Average yield and composition of milk on different grain rations.*

Period.	Grain feed per 1,000 kg. live weight.	Daily average.			Daily average per 1,000 kg. live weight.		
		Milk yield.	Fat content.	Total solids.	Milk yield.	Butter fat.	Total solids.
		<i>Kg.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Kg.</i>	<i>Kg.</i>	<i>Kg.</i>
1	8 kg. barley meal .....	17.075	3.109	11.780	32.866	1.02189	3.87403
2	8 kg. molasses-peat feed.....	14.131	3.156	11.782	27.233	.85382	3.19690
3	8 kg. fresh molasses .....	13.601	3.456	12.273	26.738	.90416	3.22616
4	10 kg. molasses and palm-nut meal..	12.694	3.379	12.242	24.478	.81870	2.98558
5	7 kg. molasses chips .....	12.770	3.621	12.528	24.811	.88416	3.08987
6	3.81 kg. molasses pulp.....	11.924	3.760	12.476	23.268	.85962	2.88314
7	8 kg. barley meal .....	13.575	3.689	12.592	26.654	.96296	3.35090

The different preparations of molasses were as a rule readily eaten, except in the case of the molasses pulp, which the cows did not appear to like well and refused to eat more than about half as much as of the other preparations. The molasses did not agree well with some of the cows. Only in the case of the liquid molasses was the whole quantity intended for each cow readily eaten. None of the molasses preparations appeared to be equal to barley meal for milk production. On the other hand, the author considers that the molasses feed favored an increase in the percentage of fat in the milk. The effect on the total solids was practically the same as on the fat.

With respect to the effect of the molasses preparations on the yield of milk, the molasses chips stood first, although the liquid molasses was nearly as advantageous. The sugar content of the milk did not appear to be affected by feeding molasses. The average sugar content of the milk of different cows showed only a maximum difference of 0.44 per cent. The butter made during the molasses feeding was in every way equal to that made on barley meal, and no difference was observed in the churning or the taste of the butter or the milk.

The 6 cows for which the data are given were likewise under experiment the year preceding (1895) and the average fat content of the milk

<sup>1</sup>In making this correction it was assumed that the difference between the production in the first and the last periods, during both of which barley meal was fed, represented the normal shrinkage due to advancing lactation; and that on a uniform ration the shrinkage from month to month would be regular. From this difference between the first and last periods the percentage of shrinkage was calculated (*i. e.*, the percentage relation of the total shrinkage to the production in the first period), and as the feeding covered 123 days this percentage of shrinkage was divided by 123, giving the percentage of shrinkage per day. With the aid of the latter the correction of the data for each period was made.

for each cow is compared with that in 1896. It is shown that in the case of every cow the milk was materially richer in fat in 1896 (when the molasses feed was fed), the average increase being 0.466 per cent. Compared with the first period, in which barley meal was fed, there was a gain in fat content of only 0.122 per cent over 1895. The author considers that the feeding of molasses preparations in 1896 increased the fat content during the period of feeding nearly 0.5 per cent over that in 1895. The relative fat content of the milk of individual cows in the 2 years was nearly the same, *i. e.*, in both years No. 1 gave the richest milk and the relative richness of the milk of the other cows was very nearly the same for both years.

*Effect of molasses in comparison with cane sugar.*—To determine whether the beneficial effect on the fat was due alone to the sugar in the molasses, an experiment was made with 2 cows covering 11 periods of 10 days each. Barley meal was fed in the first and the last 2 periods, and in other periods molasses peat feed and fresh molasses were compared with cane sugar fed alone and with palm cake and various salts (Kreuznach salts, potassium sulphate, and common salt). The results are given in detail for both of the cows. One of the cows shrunk rapidly in milk and was found later to be tuberculous. The results are briefly summarized in the following table:

*Average results with barley meal, molasses, and cane sugar.*

	Feed.	Milk.	Fat.	Total solids.
		<i>Kg.</i>	<i>Kg.</i>	<i>Kg.</i>
Average of periods 1 and 11....	Barley meal.....	20.920	0.77364	2.61281
Average of periods 2 and 4.....	Molasses.....	19.172	.73372	2.43555
Average of periods 3 and 6.....	Cane sugar, without salts.....	16.948	.66508	2.20517
Average of periods 7, 8, and 9....	Cane sugar, with salts.....	16.715	.66352	2.17841

The molasses was not quite equal to the barley meal, but was plainly superior to cane sugar. The addition of various salts to the cane sugar to approximate the salts contained in molasses appeared to have little, if any, effect on the relative results.

*Feeding molasses to cows with calf.*—Two cows in the last months of gestation were fed 8 kg. of molasses daily, per 1,000 kg. live weight, and after calving the feeding was continued. There was apparently no injurious effect from this feeding, either in the condition of the cow or the development of the calf.

In conclusion, the author expresses the belief that molasses is an advantageous, safe, and, at present local prices, cheap feeding stuff for milk production. Concerning the different forms, the experiments indicate the liquid molasses and the mixture of molasses and the residue from sugar-beet factories to be the best. Molasses-peat feed and molasses and palm cake have not given quite so favorable results, and the molasses pulp, while it gave good results, was not readily eaten by cows.

**Studies of methods of experimental feeding trials**, J. L. HILLS (*Vermont Sta. Rpt. 1896-'97*, pp. 134-169, 193-217).—This includes experiments on the proper length of feeding periods, the relative feeding value of rations with like nutritive ratios, the experimental error in feeding trials, and a comparison of Atlas gluten meal with other grain feeds. Full data are given in these experiments in the body of the article and in an appendix, and the results are summarized and discussed.

*The proper length of feeding periods* (pp. 146-161).—"So far as the writer can discover by thorough search and through consultation with others, no tests have been made showing what is and what is not a reliable period length. The short period of 1 or 2 weeks is clearly to be condemned as likely to furnish erroneous results, since the animal can hardly be said to have begun to feel the effects of the change in ration when the period is over. While such results are surely untrustworthy, it is not yet clear whether 3 or 4 weeks or more are necessary to furnish reliable data."

The experiments were made with 15 cows, divided into 5 lots of 3 each. Two different rations were fed containing corn meal and wheat bran with or without Atlas gluten meal. Lot 4 was alternated on these 2 rations for 6 periods of 4 weeks each, lot 5 for 5 periods of 5 weeks, lot 6 for 4 periods of 6 weeks, and lots 7 and 8 for 3 periods of 7 and 8 weeks, respectively. Owing to a misunderstanding lot 5 had to be reduced to periods of 4 weeks. The periods were divided into preliminary and experimental portions, the preliminary part of the period ranging from 10 days in the 4-week periods to 20 days in the 8-week periods. The nutritive ratio of the Atlas gluten meal ration averaged 1:6.6, and that of the other ration 1:10.2.

"It seems safe to assert that in these trials results essentially similar in character and extent were obtained when the Atlas ration was fed in periods from 6 to 8 weeks long as had been observed when it was fed for but 4 weeks. In other words, in this particular comparison, which it will be recollected is between a 'medium' and a 'wide' ration, feeding periods 4 weeks long gave trustworthy results as regards quantity changes. This deduction applies to the yield of milk alone and not to its quality. The effect of the Atlas ration upon the quality of the milk is considered under the next heading."

As to the effect of food on the quality of milk, an extensive résumé is given of experiments conducted in this country and abroad upon this subject, and the results in this particular experiment are summarized.

"When the Atlas ration of medium balance replaced the wide corn and bran ration for a short time (4 weeks or less) a somewhat richer milk was made, one in which the fat was increased and the solids not fat remained essentially unaffected. This effect was not observed, however, when the ration was fed 6 weeks or more, the quality remaining unaltered, or, if anything, growing a shade poorer. Nine cows fed in periods 4 weeks long testify that the quality of milk is slightly bettered, and the ratio of fat to solids not fat narrowed by the substitution of Atlas gluten meal for corn and bran in the ration. Eight other cows fed in periods from 6 to 8 weeks long testify to the contrary. . . . The upshot of these series of comparisons appears to be that the 4-week period did not give results which are entirely trust-

worthily touching the quality of the milk given on the Atlas ration. The 6-week period, however, and those yet longer in duration gave satisfactory results. Combining the conclusions on both quantity and quality, it would appear that a 4-week feeding period accurately indicated, in the present case, the character of and probably the extent of quantity changes, but that the slight improvement observed in quality was temporary and not to be relied upon as likely to continue under the conditions of prolonged feeding on a single ration. Since this latter effect is but slight and entirely without practical significance, and since the results of longer feeding discount it, one need not lose faith in the essential accuracy of past observations in which 4-week periods have been used."

*The relative feeding values of 2 rations of equal balance* (pp. 162-164).— In this experiment rations consisting of hay and silage, wheat bran, corn meal, and either 1½ lbs. each of cotton-seed meal and linseed meal or 4 lbs. of Atlas gluten meal were fed. The aim was to feed as nearly as possible the same amounts of digestible protein in the two rations, but, as a matter of fact, the amounts fed differed by about 5 per cent in favor of the oil-meal ration. The nutritive ratio of the oil-meal ration was 1:6.3 and of the Atlas meal ration 1:7.3. Nine cows were used in the experiment. They were alternated on the 2 rations for 5 periods, varying from 4 to 7 weeks each in length. Based on the 331 days of feeding, the following conclusions are drawn:

"Four per cent more dry matter eaten in the form of the Atlas ration than was eaten in the form of the cotton-seed-linseed ration produced 1 per cent more milk, but no more solids or fat. The milk made on the cotton-seed-linseed ration was somewhat the richer of the two, but the enrichment could hardly be termed one-sided, the ratio of fat to solids not fat narrowing very slightly (Atlas 1:1.71, cotton-seed-linseed 1:1.68).

"One hundred pounds of dry matter, both in the entire ration and in the grain portion thereof (experimental portion), proved more efficient in the cotton-seed-linseed than in the Atlas ration, making on the average about 6 per cent more product. This increase is not sufficient to warrant great stress being laid upon it, yet, because of the large number of cows used and the almost perfect uniformity of the trend in each individual case, it is thought that the difference lies outside the pale of possible experimental error and that it is mainly a food effect. The dry matter of the rations being of nearly equal digestibility (cotton-seed-linseed 75, Atlas 76), the conclusions in the last paragraph may properly be applied likewise to digestible dry matter.

"It has already been pointed out that the excess of protein in the cotton-seed-linseed ration was but 5 per cent. In these cases of essentially equal consumption of protein one ration proved somewhat more effective than another. The ration containing the most digestible carbohydrates, the most digestible fat, and the most digestible dry matter gave the smallest returns."

*Experimental error in feeding tests* (pp. 165-167).—

"The question has been raised whether differences obtained in feeding various rations, one against another, are not frequently due to causes other than changing food, even where every precaution is taken to render all other conditions uniform. In order to test this point a repetition of previous experiments made at this station, consisting of the uniform feeding of cows for several months, was carried out with 9 cows. Practically no change occurred in quantity or quality of product on a uniform ration. A pound of total dry matter produced as much milk, total solids and fat, at one time as at another, lactation stages being equalized. It is thought, however, that if but few animals are used it is unsafe to claim that changes in product of less than 5 per cent are of necessity due to changes in feeding."

*Practical conclusions of economic value* (pp. 167-169).—The above experiments afforded an opportunity for comparing Atlas gluten meal with corn meal and bran and with cotton-seed and linseed meal. The results are summarized below:

*Comparisons of corn and bran, Atlas, and cotton-seed-linseed rations.*

Ration.	Food eaten.					Production.			Cost of food.	
	Hay.	Corn meal.	Wheat bran.	Atlas gluten meal.	Cotton-seed-linseed meal (equal parts).	Silage.	Milk.	Butter. <sup>1</sup>	Per 100 lbs. of milk.	Per lb. of butter.
	<i>Lbs.</i>	<i>Lbs.</i>	<i>Lbs.</i>	<i>Lbs.</i>	<i>Lbs.</i>	<i>Lbs.</i>	<i>Lbs.</i>	<i>Lbs.</i>	<i>Cents.</i>	<i>Cents.</i>
Atlas meal.....	5,539	612	613	3,309	.....	19,812	12,047	665	77.8	14.1
Corn and bran.....	5,231	2,166	2,166	.....	.....	18,781	10,152	557	84.7	14.9
Atlas meal.....	3,693	810	1,215	1,620	.....	13,606	5,221	332	127.8	20.1
Cotton-seed-linseed meal.....	4,283	869	1,303	.....	1,304	15,589	5,879	377	128.5	20.0

<sup>1</sup>One and one-sixth times the fat.

“The Atlas ration was more economical than the corn and bran ration. More milk was made thereon, and the food cost more; hence the milk was made but 8 per cent and the butter but 6 per cent cheaper on the richer ration. Atlas gluten meal at \$16 is not much cheaper than corn and bran at \$15 and \$13, respectively.

“Apparently the cotton-seed-linseed ration made more milk and butter than the Atlas ration, and cost more. The periods, however, were of different lengths, and the animals were fed some 3 and some 5 periods; hence the figures are in reality useful only as means to arrive at the cost of food per unit of production. In this respect absolute equality is found. So far as can be judged under the somewhat irregular conditions of this test, the 2 rations were financially of equal value.”

The fertilizing value of the different rations is considered.

**Some observations on the relation between body conformation and production in cows**, E. A. BOGDANOW (*Jour. Landw.*, 15 (1897), No. 3-4, pp. 271-293, pl. 1).—The author made various measurements on 80 cows of the herd at Tapiau, whose record for several years was known. The method of measurement followed was that described by Werner.<sup>1</sup> Various groups were formed according to the production of milk, butter, etc., and the measurements of the cows in the different groups were studied and compared.

From the results the author concludes that a close relation between external conformation and production is so apparent as to be unmistakable. Furthermore, so far as could be judged from special studies of early and late maturing cows, it appeared that the best yields were obtained from cows which matured relatively early.

**Experiments on the effect of different grain and concentrated feeds on the milk production of cows**, RAMM (*Landw. Jahrb.*, 26 (1897), No. 4-5, pp. 693-731).—This experiment was with 2 lots of 5 cows each, and included trials of 18 different grain rations, each fed in addition to a basal ration of 14 kg. of hay, 6 kg. of straw, and 50 kg. of

<sup>1</sup>H. Werner, Rindzucht, Berlin, 1892.

beets per 1,000 kg. live weight. The grain feeds tested were rape cake, linseed meal, peanut cake, cotton-seed meal, sunflower meal, poppy cake, cocoanut cake, palm cake, dried brewers' grains, wheat meal, oatmeal, rye meal, corn meal, barley meal, wheat bran, rye bran, molasses and palm cake (1:1), and malt sprouts. With one lot the feeding commenced with the various meals and ended with the oil cakes, etc., and with the other the oil cakes were fed first. The periods were only 10 days each, except in 2 cases, with no transition periods intervening. Only the last 5 days were considered in studying the effect of the food. The rations usually contained about 2 kg. of digestible protein per 1,000 kg. live weight, although in a number of periods the amount dropped to 1.5 kg. and even lower. Consequently the nutritive ratios ranged from 1:6.5 to 1:12.4. The cows were weighed every other day and the yield and composition of the milk determined daily. The detailed data are tabulated.

The cows at first refused to eat the rye meal, but on the fifth day of the period commenced eating small amounts, the maximum consumption being about 12 kg. daily per 1,000 kg. live weight. The case was similar with rye bran, of which only 8.73 kg. was eaten.

The author found no relation between the fat content of the milk and the amount of fat contained in the rations, as has been suggested by Soxhlet (*E. S. R.*, 8, p. 1016).

The author groups the feeding stuffs tested under three heads—those advantageous, those disadvantageous, and those indifferent in their effect on milk production. Among those advantageous to milk production were the mixture of beet molasses and palm cake, barley meal, malt sprouts, linseed meal, corn meal, wheat bran, and oatmeal in the order named. The mixture of molasses and palm cake had the greatest effect of any food on the solids and fat content. It was only disadvantageous to the increase in live weight. It is thought this may be due to the effect of the molasses on the kidneys, as suggested by Hagemann (see above). Barley meal was found a desirable food in every respect. On corn meal the yields of milk, solids, and fat were high, although the percentage of solids and fat was not noticeably high.

Among those disadvantageous to milk production were cocoanut cake, poppy cake, sunflower meal, peanut meal, cotton-seed meal, and rye bran. With cocoanut cake the results were unfavorable in almost every respect, due possibly to the fact that the animals ate only about half the amount which it was intended to give them. Poppy cake ranked poorest of all in respect to the fat and solids, both the percentage and the total amount. Sunflower meal, while not especially unfavorable, did not give satisfactory results. The peanut meal was especially disadvantageous to the content of solids and fat, while the yield of milk was only a little below the average. The same was true with cotton-seed meal, and in case of 2 of the cows inflammation of the udder was noticed. (About 3.6 kg. of cotton-seed meal per 1,000 kg.

live weight was fed.) The rape-seed cake, wheat meal, rye meal, palm cake, and dried brewers' grains had no particular effect upon milk production as a whole. The palm cake, although it gave a high percentage of fat, was not satisfactory in other respects. The milk had an oily odor and a pungent taste.

**Feeding experiments with milch cows**, J. M. BARTLETT (*Maine Sta. Rpt. 1896*, pp. 37-55).—In these experiments gluten meal was compared with cotton-seed meal, silage was compared with grain, and ground oats was compared with wheat bran, and the effect of Nutriotone was tested. Six registered Jersey cows were used, and these were divided into 2 lots of 3 each.

*Gluten meal vs. cotton-seed meal* (pp. 39-43).—Feeding a constant basal ration, 3 lbs. of gluten meal was compared with 2 lbs. of cotton-seed meal in 3 periods of about 3 weeks each. The composition of the feeding stuffs and of the milk, with other data, are tabulated.

"The data indicate that gluten meal is fully equal to cotton-seed meal when fed in sufficient quantity to make the amount of digestible nutrients equal in each ration. It is not equal to cotton-seed meal pound for pound as a source of protein, as it contains, on an average, about one-quarter less of that nutrient. It makes a very good quality of butter, but slightly softer than that made from cotton-seed meal ration when fed in the quantity used in this experiment."

*Silage compared with grain* (pp. 43-46).—The silage was the Robertson mixture, consisting of fodder corn, horse beans, and sunflower heads. Ration No. 1 consisted of 20 lbs. timothy hay, 20 lbs. silage, and 8 lbs. grain. Ration No. 2 consisted of 15 lbs. timothy hay, 35 lbs. silage, and 4 lbs. grain. There were 2 periods of 2 weeks each.

"This experiment, although too limited to be of much value in itself, confirms the results of Professor Robertson's investigations and those obtained from experiments made at this station last year, showing that silage of the quality used can be substituted in part for the grain ration of milch cows without causing loss of flesh or lessening the production of milk. In this case 15 lbs. of silage appeared to equal 4 lbs. of the grain mixture."

*Ground oats compared with wheat bran* (pp. 46-51).—Feeding a constant basal ration, 4 lbs. of wheat bran was compared with 4 lbs. of ground oats in 3 periods of about 3 weeks each.

"These results show a slightly larger yield when oats were fed than when bran was fed, but the differences are not sufficiently large for one to say that oats have a greater feeding value than bran. . . . Their mechanical condition is such that they are equally good to mix with heavier feeds like corn, cotton seed, and gluten meals."

*Nutriotone for the production of milk* (pp. 51-55).—This material is said to be extensively advertised in the State, and the claim made that it is not only a curative agent but a stimulant to the production of flesh and milk. Five Jersey cows, fresh in milk, were fed liberal rations of hay and grain in proportion to their size; and, in addition, in the first, third, and fifth periods, the prescribed amount of Nutriotone was fed, and in

the fourth period 2 spoonfuls of linseed meal in each feed was substituted for it. The results are summarized as follows:

*Summary of results with and without Nutriotone.*

	Milk.	Butter fat.
Average for 21 days without Nutriotone.....	<i>Pounds.</i> 2, 281	<i>Pounds.</i> 101
Average for 21 days with Nutriotone.....	2, 264	101

“In neither of these cases did Nutriotone seem to have any effect, favorable or unfavorable. The slightly smaller milk flow with Nutriotone does not mean anything in particular except to add increased emphasis to the falseness of the claim that 2 large tablespoonfuls fed with each feed ‘will produce a great increase of much richer milk.’”

Remarks are made on the use of condimental food, and a tonic is recommended for use when animals are out of condition and in need of such treatment.

**The food requirements and production of different breeds of cows,** R. GRIPENBERG (*Tidn. Mjölkhushall., 6 (1897) Nos. 31-37*).—The paper gives a discussion of the comparative economy and productive capacity of Holstein, Ayrshire, Angler, and Finnish breeds of cows and of crosses, kept at the Mustiala Agricultural and Dairy Institute, from 1885-'96. Tables giving the amounts of hay and concentrated food consumed and milk produced during each year for the various breeds are included in the paper. The quality of the milk produced was unfortunately only ascertained during 4 years, 1889-'91 and 1896. The members of “food units” given in the table refer to hay and concentrated food consumed, the value of the former being considered one-half that of the latter. Pasturage was the same for all cows, and the quantities of straw and roots (or silage) eaten were considered compensated for by the manure produced by the cows.

*Production and relative economy of different breeds of cows.*

Breed.	Average number of cows, 1889-'96.	Per cow per year, 1885-'96.					Food units required per—	
		Hay.	Concentrated food.	Food units.	Milk produced.	Fat content (4 years).	100 kg. milk.	1 kg. cream (3 years).
		<i>Kg.</i>	<i>Kg.</i>		<i>Kg.</i>	<i>Per cent.</i>		
Holstein.....	10	1, 625	519	1, 331	3, 159	3. 0	42. 2	9. 6
Ayrshire.....	24	1, 483	416	1, 157	2, 376	3. 6	49. 0	8. 6
Angler.....	7	1, 449	407	1, 132	2, 330	.....	48. 7	10. 1
Crosses.....	11	1, 539	475	1, 244	2, 789	3. 4	45. 0	.....
Finnish native.....	13	1, 373	379	1, 070	1, 892	3. 6	56. 1	9. 8

Valuing a food unit at 2 cts., milk at 2 cts. per kilogram, butter at 43 cts. per kilogram, and skim milk at 0.6 ct. per kilogram, the author arrives at the following figures, which indicate the profit per year and per cow for the different breeds: Holstein \$38, Ayrshire \$33, Angler \$26.50, crosses \$38, and Finnish native \$23.—F. W. WOLL.

**Feeding trials with silage and potatoes,** J. L. HILLS (*Vermont Sta. Rpt. 1896-'97, pp. 169-174, 218-220*).—A comparison was made with 2 cows of corn silage and a silage made from a mixture of cowpea vines and soy beans. At the time of ensiling the mixed silage contained about 23 per cent of crude protein in dry matter, while the corn silage contained about 11 per cent.

“The mixed silage lost very heavily of its protein in the silo, however, and came out hardly richer in that ingredient than was its competitor. The reasons for this loss are not clear. The corn silage in another portion of the same silo kept nicely. . . .

“Less but better milk and essentially equal yields of solids and fat were made from somewhat more total dry matter on the soy bean-cowpea silage than when corn silage was fed. One hundred pounds of dry matter in corn silage proved superior to the same amount in the mixed silage. The mixed silage analyzed but little better than the corn silage, cost more to grow and harvest, yielded less, and was distasteful to some cows. The marked increase in the quality of the milk following the feeding of the mixed silage, while suggestive, is not thought to be due as much to change of feed as to a coincident shrinkage in the milk flow.”

Corn silage and potatoes were compared in an experiment with 6 cows, covering three 4-week periods.

“The cows ate more freely of the potatoes than of the silage and while on the potato ration consumed more dry matter, yet in 5 out of 6 cases they made no more milk and in one case but little more. The milk did not change in quality and essentially equal quantities of total solids and fat were produced on each ration. Since increased production did not follow the more hearty eating, a pound of dry matter in the form of potatoes was less effective than a similar amount of dry matter in the form of silage. Potatoes at 15 cts. a bushel are more costly as stock food than silage.”

**Record of the station herd for 1895-'96,** J. L. HILLS (*Vermont Sta. Rpt. 1896-'97, pp. 181-188*).—The record is given for 37 cows from November 1, 1895, to October 31, 1896:

“As a herd the average cost of food for 100 lbs. of herd milk was 77.3 cts. and for a pound of butter, 13 cts. . . . Twenty-eight of the individual cows whose records appear in the preceding table, together with 2 others, formed the herd of which the record was published in our last report. Comparing the records of the 2 years we find that 12 cows gave more, 2 the same, and 14 less milk the second year than they did the first; that 12 gave more, 2 the same, and 14 less butter in 1895-'96 than in 1894-'95; while 11 gave better, 10 poorer, and 7 the same quality of milk in the latter as compared with the former year. The average for the 28 cows shows almost exactly the same production each year, but at greatly reduced cost during the latter year.”

*Average record of twenty-eight cows for two years.*

Year.	Yield of milk.	Fat content of milk.	Yield of butter.	Cost of food.	Cost of purchased grain.	Cost of food per lb. butter.	Proceeds of butter sales.
	<i>Pounds.</i>	<i>Per cent.</i>	<i>Pounds.</i>			<i>Cents.</i>	
1894-'95.....	5,616	5.02	329	\$50.36	\$18.92	16.2	\$77.18
1895-'96.....	5,586	5.03	328	43.72	14.49	14.1	75.48

"It is again shown that the Ayrshire cow is more successful as a milk maker than as a butter producer. As a general rule the cows making the most butter were the most economical producers. The larger cows, which ranked well in gross amounts of butter made, graded lower in most cases in economy of production, while the smaller cows, which stood near the head in amount of butter made, did not lose rank in the matter of cheap manufacture. In other words, the well-known fact that the smaller cow usually makes the cheapest butter is again demonstrated."

**The effect of food upon the quality of butter, J. L. HILLS** (*Vermont Sta. Rpt. 1896-97, pp. 175-181*).—In connection with some of the experiments described above, studies were made of the effect of the rations upon the quality of the butter and upon churnability. The scoring and the chemical analysis of the butter are given and the data for churning. The results are briefly summarized as follows:

"*Effects upon butter.*—Butter made from a ration containing large amounts of potatoes was of poor quality, tended to be salvy and did not keep well. It showed, upon chemical analysis, a medium amount of volatile acids, but a very low iodine number.

"Butters made from 3 hay and silage rations, containing respectively large amounts of corn and bran, of Atlas gluten meal, and of cotton-seed and linseed meals, were scored by experts essentially alike. The butter made upon the rations containing relatively large amounts of Atlas gluten meal was judged by the station dairyman to be on the whole a shade inferior to the others, particularly in grain. The only marked difference developed on chemical analysis concerned the iodine number, which in the Atlas butter was uniformly high, indicating probably an increased percentage of olein.

"*Effects upon churning.*—The creams from the milks made on the Atlas ration invariably churned less exhaustively than those made upon either the corn and bran or the cotton-seed-linseed rations, all other conditions being equalized. No plausible reason other than that of food effect presents itself, yet the writer feels unwilling as yet to assert that the Atlas ration was at fault in the matter."

**Report of the dairy investigator, F. B. LINFIELD** (*Utah Sta. Rpt. 1897, pp. 51-60*).—Remarks on the work of the division, an experiment with pasturage for cows, variations in the fat content of milk, and the value of by-products of the dairy for feeding pigs (see p. 871). Trials for 2 summers with 2 cows showed the advantages of properly seeded pastures for dairy cows as compared with the ordinary range. "It would take a yield of from 48 to 62 bu. of wheat per acre, at average prices for the past 3 years, to return as much as could be made by pasturing cows." The variations in the fat content of the first milk and strippings, the morning's and night's milk and that from day to day, and in the herd milk, with advancing lactation, are illustrated. The failure to recognize these normal variations is believed to be a frequent cause of dissatisfaction with the method of paying for milk by test.

**Preliminary investigations concerning the number and nature of bacteria in freshly drawn milk, V. A. MOORE** (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 261-266*).—Bacteriological examinations were made of the milk of 9 cows. The teats and udders of the cows and the hands and arms of the milkers were

washed with a dilute solution of corrosive sublimate, and the milk was drawn directly into sterilized bottles.

"In collecting the milk, from 5 to 10 cc. of the fore milk was taken in separate bottles from each quarter of the udder and about 50 cc. near the close of the milking, except in 5 cases. The milk was taken directly to the laboratory and agar plates (in a few instances gelatin plates also) were made with definite quantities (from 0.1 to 1 cc.) of the milk."

The number of colonies found in each case are tabulated. This shows that "in every case bacteria were found in the last milk taken from one or more quarters of the udder."

"These results, as well as those heretofore reported, show an almost constant appearance of bacteria, often in small numbers to be sure, in the milk taken during the last part of the milking. . . .

"The properties of the bacteria found in the fore milk are of more importance than their numbers. . . . A thorough differential study of the bacteria which I have found in freshly drawn milk has not been completed. In all, 20 apparently different species were isolated. Of these, 3 were streptococci, 4 bacilli, and 13 micrococci. Among the bacilli *Bacillus cloacæ* occurred in one specimen. It is possible, as it occurred but once, that it was an accidental contamination from external sources. This was the only gas producer in the entire series. Nine of the apparent species were aerobic, indicating their presence near the end of the teat or milk duct, and the others were facultative anaerobic, and could have come from much higher up in the teat.

"With one exception the organisms isolated fermented lactose in both bouillon, to which chemically pure lactose had been added, and in milk itself, giving a decidedly acid reaction. . . . Six of the 20 species produced a firm coagulation of the milk within 20 hours. The others precipitated or coagulated the casein in from 4 to 10 days. . . .

"The pathogenesis of these organisms was tested by the subcutaneous inoculation of 0.5 cc. of a fresh bouillon culture into guinea pigs, but invariably the animals remained well. In fact, a perceptible local lesion was not produced in any case. . . .

"[In view of the fact that the number of lactic acid bacteria in fresh milk appeared to increase rapidly] it seems very important that milk should be pasteurized, if its normal composition is to be retained, as soon as possible after being drawn. Milk that has stood under ordinary conditions for from 4 to 12 hours before its bacterial flora is destroyed must necessarily have undergone more or less deleterious changes, the extent of these alterations depending upon the temperature at which it is kept and the number and nature of the bacteria in the fore milk. It is well known that all milk pasteurized after it is delivered by the milk vender does not agree with all children."

**The double-necked Babcock bottle for testing skim milk and buttermilk,** M. E. McDONNELL (*Pennsylvania Sta. Rpt. 1896, pp. 221-224*).—A series of 10 tests was made on 12 samples of skim milk of different fat content, using the double-necked test bottle described by Farrington.<sup>1</sup> The method was found satisfactorily uniform for the same sample. All the results were believed to be slightly low on account of a small quantity of the fat remaining in suspension and a minute quantity probably being dissolved by the acid. Skim milk

<sup>1</sup> Wisconsin Sta. Bul. 52 (E. S. R., 8, p. 932).

found by analysis to contain 0.16 per cent of fat was diluted with known quantities of water and with milk and the fat determined by test and by analysis. "The double-necked Babcock bottles gave results 0.01 per cent lower than the calculated amount, and 0.08 per cent lower than those actually obtained by gravimetric analysis."

In conclusion the results obtained with a double-necked bottle by Farrington are quoted.

**Creameries or butter factories; advantages, location, organization, and equipment,** H. E. ALVORD (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 297-316, pls. 7, figs. 4*).—After brief introductory remarks the author treats of the extent of the creamery system in different States, the advantages of creameries, location, methods of operation, and the construction and equipment of creameries, giving illustrations and plans of creameries, and accounts of the operations of a number of creameries. The appendix contains blank articles of agreement for creameries, by-laws of creamery associations, and a statement of the principal apparatus needed to equip a butter factory for 500 cows or less.

**Composition of full-cream cheese,** W. FREAR (*Pennsylvania Sta. Bul. Inf. 2, pp. 16*).—This is a compilation of work at the stations in New York, Wisconsin, Iowa, and Minnesota, and at the Ontario Agricultural College, together with a statement of the requirements of the Pennsylvania cheese law, passed June 23, 1897. This law divides cheese into 5 grades according to its fat content as follows: Full cream, with not less than 32 per cent of fat; three-fourths cream, with not less than 24 per cent of fat; one-half cream, with not less than 16 per cent; one-fourth cream, with not less than 8 per cent; and skimmed cheese, including all cheese with less than 8 per cent of fat.

"(1) Experiments on a large scale in 5 States and Provinces show that average factory milk very rarely produces green cheese containing less fat than the Pennsylvania legal standard for full-cream cheese, viz, 32 per cent.

"(2) Four sets of experiments show that the green cheese loses about 5 per cent in weight during 1 month's curing, and that this loss is chiefly in the water content of the cheese. Consequently, a green cheese containing only 30.5 per cent of fat will probably be of standard "full cream" quality after 1 month's curing.

"(3) Neither minor variations in manufacture—providing gross carelessness be avoided—nor variations in the factory milk supply, unless it include much partly skimmed milk, are to be feared as a cause of deficiency in fat."

**Care of milk on the farm,** R. A. PEARSON (*U. S. Dept. Agr., Farmers' Bul. 63, pp. 38, figs. 9*).—This bulletin calls attention to bacteria as the cause of milk fermentations, the conditions affecting bacterial growth, the number and kinds of dairy bacteria, and the ways in which milk becomes impure—(1) diseased animals and persons and unnatural conditions, (2) uncleanness in the stable, and (3) uncleanness outside the stable; and discusses the means of keeping milk pure by maintaining healthy cows, cleanliness in the care and handling of the animals and in the employees; the construction of dairy houses; and milking, aerating, and cooling milk and storing it. In conclusion 50 dairy rules are given which are based on the text of the bulletin.

**Dairying in Oregon,** H. T. FRENCH, G. W. SHAW, and F. L. KENT (*Oregon Sta. Circ. 1, pp. 32, pls. 2, figs. 5*).—This is a popular article treating of grasses and for-

age plants, principles of cattle feeding, chemistry of milk, milk testing, practical butter making, etc.

**Fodder crops for cattle on a 40-acre lot**, W. SAUNDERS (*Canada Expt. Farms Rpts.* 1896, pp. 75-80).—During the first year of the experiment 14 cows were kept on the produce of a 10-acre lot, during the second year 23, the fourth year 25, and the fifth year 21. The bedding used was not obtained from the lot. During the third year the experiment was interrupted.

**Sunflower-seed cake for milch cows**, HERTER (*Molk. Ztg.*, 11 (1897), No. 52, pp. 848, 849).—A trial of feeding sunflower-seed cake to a herd of cows in connection with roots and wheat bran, resulted in the production of a very soft butter, which was troublesome even in winter.

**On the effect of various grain foods on the milk production of cows** (*Milch Ztg.*, 26 (1897), Nos. 43, pp. 679-682; 44, pp. 697-700; 45, pp. 713-716).—A short account of work by Ramm reported from another source (see p. 879).

**Contribution to the rational feeding of cows** (*Milch Ztg.*, 26 (1897), No. 51, p. 815).—A brief account of investigations by Ilagemann already abstracted from another source (E. S. R., 7, p. 237; 8, p. 788).

**The practical and industrial control of milk**, P. DORNIC (*Le control pratique et industrielle du lait. Mamiolle, 1897; rev. in Jour. Hyg.*, 22 (1897), No. 1097, p. 466).—Among other matters the author discusses the different apparatus used and methods employed in detecting fraud in handling milk.

**The water content of butter**, A. HALENKE (*Forsch. Ber. Lebensm.*, 4 (1897), No. 12, pp. 347-350).

**Matzoon**, B. MARTINY (*Milch Ztg.*, 27 (1898), No. 1, p. 6).—It is noted that in Armenia, where kephir does not occur, the organisms used in preparing matzoon from milk are also used for ripening cream.

**Milk somatose**, A. BRESTOWSKI (*Pharm. Ztg.*, 42 (1897), p. 845; *abs. in Chem. Ztg.*, 21 (1897), No. 103, *Reper.*, p. 325).—This is a food preparation similar to somatose made from meat but made from milk and containing 5 per cent of tannin. It is a fine yellowish powder, very soluble in water. The method of preparation is not given.

**Unorganized ferments of milk—a new factor in the ripening of cheese**, S. M. BARCOCK and H. L. RUSSELL (*Centbl. Bakt. u. Par.*, 2. *Abt.*, 3 (1897), p. 617; *abs. in Chem. Ztg.*, 22 (1898), No. 3, *Reper.*, p. 14).

**The microscopic examination of butter for bacteria, especially Bacillus tuberculosis**, O. ROTH (*Worbl. Schweizer Aerzte, 1897, No. 18, p. 545; abs. in Hyg. Rundschau, 7 (1897), No. 24, pp. 1263, 1264*).

**Preservation of cream for market**, F. L. RUSSELL (*Maine Sta. Rpt. 1896, pp. 141-145*).—A reprint of Bulletin 23 of the station (E. S. R., 7, p. 992).

**The "latent" coloring of margarin**, H. SCHROTT (*Milch Ztg.*, 26 (1897), No. 47, p. 746).—A condensed account of a pamphlet recently published by the author. The proposed plan is discussed by requiring the addition of sesame oil to margarin, since this oil can be easily detected by the color it gives in the test, and so furnishes a means of recognizing margarin. It is believed, however, that coloring with phenolphthalein furnishes greater protection to consumers.

**The examination of margarin and butter for sesame-oil content**, P. SOLTSIEN (*Pharm. Ztg.*, 42 (1897), p. 837; *abs. in Chem. Ztg.*, 21 (1897), No. 103, *Reper.*, p. 325).

**Inspection of glassware used by creameries and butter factories to determine the value of cream and milk**, J. M. BARTLETT (*Maine Sta. Rpt. 1896, pp. 150-153*).—A reprint of Bulletin 26 of the station (E. S. R., 8, p. 172).

**A modification of the Babcock method and apparatus for testing milk and cream**, J. M. BARTLETT (*Maine Sta. Rpt. 1896, pp. 165-172, figs. 2*).—A reprint of Bulletin 31 of the station (E. S. R., 9, p. 184).

**An improved milk scale**, H. D. RICHMOND (*Analyst, 23 (1898), Jan., p. 2*).—This improvement permits the operator to determine the density of the milk without previous reduction to the normal temperature.

**A calculation of the total solids of milk**, M. E. McDONNELL (*Pennsylvania Sta. Rpt. 1896, pp. 82-84*).—The method of calculating the total solids of milk by means of the Hehner and Richmond formula is described and a table is given showing the percentage of total solids in milk corresponding to the Quevenne lactometer reading and percentage of fat.

**Graduation of the Leffmann-Beam bottles**, G. E. SCOTT-SMITH and A. B. SEARLE (*Analyst, 23 (1898), Jan., p. 3*).—The use of alcohol instead of mercury or water is recommended in calibrating the bottles.—L. H. MERRILL.

**Test of separators**, J. M. BARTLETT (*Maine Sta. Rpt. 1896, pp. 35, 36*).—Four tests are reported with United States Separator No. 5, 4 with DeLaval Baby No. 2, and 3 with Empire No. 5. "The operator could detect no material difference in the ease of running of the United States No. 5 or Baby No. 2. The Empire being a larger machine, of course ran harder. He, however, preferred the United States to the others on account of the simplicity of the bowl, it requiring less time to set it up clean, etc."

**A test of hand separators**, H. HAYWARD (*Pennsylvania Sta. Rpt. 1896, pp. 57-78*).—A reprint of Bulletin 38 of the station (E. S. R., 9, p. 386).

**Tests of dairy apparatus**, J. L. HILLS (*Vermont Sta. Rpt. 1896-'97, pp. 191, 192*).—Results are given of tests of the following separators: DeLaval Alpha, Baby No. 2 and No. 3; DeLaval Alpha, Dairy Turbine No. 3, DeLaval Alpha, Humming Bird, Empire No. 5 and No. 7 (Mikado); Sharpless Safety, Hand, United States No. 3 and 5, and United States No. 7 (Midget).

**Gouda cheese**, H. HAYWARD (*Pennsylvania Sta. Rpt. 1896, pp. 79-81*).—The method of making Gouda cheese is described and references made to some preliminary trials conducted at the station. "In these preliminary trials 100 lbs. of milk, testing about 5 per cent fat, yielded 14 lbs. of green cheese. The amount this will cure out will depend somewhat on circumstances. Some experiments state that in 2 months the cheese would lose about 17.5 per cent of its weight."

**The constitution of milk with special reference to cheese production**, S. M. BABCOCK (*Wisconsin Sta. Bul. 61, pp. 21, figs. 3*).—This is a popular bulletin on the yield, physical constitution and composition of milk, the fat globules and other constituents of milk, conditions affecting the composition, relative value of milk, relation of milk constituents to cheese, and the calculation of the yield of cheese. Under the latter head a table is given showing the yield of cheese from 100 lbs. of milk corresponding to different fat contents from 2 to 6 per cent and different lactometer readings.

The author mentions the finding of soluble ferments in milk as normal constituents by H. L. Russell and himself (E. S. R., 9, p. 205).

## VETERINARY SCIENCE AND PRACTICE.

**Investigations of diseases of domestic animals**, T. SMITH (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 119-183, pls. 5*).—*Notes on sporadic pneumonia in cattle: Its causes and differentiation from contagious pleuropneumonia* (pp. 119-148, pls. 4).—The causes and characteristics of sporadic pneumonia and epizootics of infectious pneumonia are discussed and a description given of the bacteria associated with the disease, and some points of difference between sporadic broncho pneumonia and contagious pleuropneumonia. In conclusion it is stated that sporadic pneumonia in cattle generally occurs as broncho-pneumonia, which may be complicated by emphysema and by interlobular trouble which simulates contagious pleuropneumonia. Broncho-pneumonia as a cattle disease is comparatively rare, and is probably due to the entrance of fluids into the air tubes during drenching.

When secondary to tuberculosis, foreign bodies, etc., these cases are easily recognized.

Nothing definite is known relative to traumatic or transit pneumonia due to blows on the thorax. The interlobular disease and the persistence and existence of lung disease are apparently to be attributed to bacteria of the swine plague group present in broncho-pneumonia in pure cultures found in healthy cattle in the upper air passages. Most of the cultures made from the parenchyma, interlobular fluids, and exudates in interlobular pneumonia remain sterile. Other differences than the bacteria of bovine pneumonia being more frequently provided with a capsule than those found in swine are not constant. Outbreaks of infectious pneumonia and septicæmia in calves are thought mostly due to highly virulent rays of the same group of bacteria.

*Two varieties of the tubercle bacillus from mammals* (pp. 149-161).—An account is given of an investigation of a bacillus from an animal of the bear tribe (*Nasua narica*) and from a bull. The morphological and other characteristics seem to indicate differences in the germ which the author seems inclined to believe to be valid. He points out the necessity for more information on the existence of races of tubercle bacilli (both human and bovine).

*Notes on the evolution of hog cholera outbreaks* (pp. 161-166).—The conclusions arrived at are that swine themselves are the chief carriers of the infection. The custom of not immediately removing dead hogs from the neighborhood of the living is deprecated; that the disease may be perpetuated and spread by preventive inoculation with living cultures; that the waves of epizootics which sweep over the country at long intervals are probably to be attributed to a sudden increase in virulence of the specific bacilli after they have passed through the bodies of swine for several years; that pathogenic bacteria are always a menace.

*Swine erysipelas or mouse septicæmia bacilli from an outbreak of swine disease* (pp. 166-174).—A somewhat detailed account is given of the morphological, biological, and pathogenic action of this bacillus which was not definitely proved to be pathogenic toward swine. Attention is called to the importance of rational feeding as a preventive in regions infected with certain diseased germs.

*Notes on peculiar parasitic infections of the liver in domesticated animals* (pp. 174-179).—The frequent existence of minute focal lesions in the liver of some domestic animals which may in all cases be due to ova of parasites or disintegrated particles of the same brought in from the digestive tract is shown to complicate the diagnosis of disease, since such lesions may sometimes be attributed to tuberculous, glanders, or other serious affections.

*Two cases of cirrhosis of the liver* (pp. 179-183, pl. 1).—A semipopular description of a case of cirrhosis of the liver in a steer and of one in the liver of a horse.

**Infectious leukaemia in fowls—a bacterial disease frequently mistaken for fowl cholera**, V. A. MOORE (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 185–205, pls. 6*).—A description is given of several cases of leukaemia and of the specific micro-organism, *Bacterium sanguinarium* n. sp., that causes it. The cultural characteristics, pathogenesis, constancy of virulence, symptomatology, morbid anatomy, etiology, and differential diagnosis, prevention, and treatment are discussed. The disease differs from fowl cholera in the intestines being pale, intestinal contents normal, lungs normal, and in the specific organisms being comparatively few in the blood. The specific organism differs from the bacterium of fowl cholera by usually appearing in pairs united end to end or in clumps, by rarely staining at the poles and saponifying milk, by its resistance to drying from 8 to 12 days, by killing rabbits inoculated subcutaneously in from 6 to 10 days instead of from 18 to 24 hours, and in not killing fowls when injected subcutaneously in small quantities. The best remedy noted is cleanliness. A mixture of equal parts of carbolic acid and sulphuric acid, among other things, is recommended as a disinfectant.

In conclusion it is stated that some cases popularly called fowl cholera are not fowl cholera, but a disease resembling it in certain symptoms and in its fatality, and differing from it in its morbid anatomy and specific organism. This specific organism in its physiological properties resembles somewhat closely *Bacillus typhosis*. The disease seems to be more prevalent than fowl cholera and old fowls seem more susceptible to it than chicks.

**Leeches**, P. A. FISH (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 229–259, pls. 7*).—This is an historical investigation of two cases of equine mycosis, with an historical account of a supposed similar disease called bursattee, occurring in India. The geographical distribution, histology, pathology, and anatomy are discussed.

Under the head of "Some other diseases of mycotic origin" are described actinomycosis, Madura disease (mycetoma), pathogenic blastomycetes, and oedema mycosis (South African horse sickness). In his general summary of the paper the author notes that he reports for the first time the presence of a fungus in "leech" tissue. The fungus is found in the inflammatory growth and may, though rarely, be seen ramifying into adjacent tissue. The fungus appears in various forms, evacuated and shrunken, branching irregularly, and sometimes with a transparent gelatinous sheath around the mycelial axis. Two kinds of wandering cells were observed—one containing numerous spore-like bodies, the other large numbers of vacuoles. The latter kind were the most numerous. Bacilli staphylococci and streptococci were found, but the author thinks they have no etiological relation to the disease.

Although they were not found, spores are thought to exist. The fungus or its spores, it is thought, enter the body either through the

mouth or through some abrasion of the skin, or both. The disease affects the subcutaneous tissue in the less vascular parts of the body. Assuming that bursattee and leeches are similar, the disease attacks both mules and cattle instead of mules alone, as in India. The American form of the disease is the more virulent. Compared with actinomycosis, leeches exhibits a preference for the equine family where the former prefers cattle. Finally the author assumes that the fungus may exist on plants, in the air, and in water. He was not able to learn of any cases of human infection.

**An outbreak of a nonspecific disease among swine, V. A. MOORE** (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 219-227*).—Following a few general remarks it is noted that the existence among swine of large numbers of destructive enzootic diseases that are not contagious, and therefore are limited in their spread, is very probable. Outbreaks of such diseases appear to be more frequent in the West, where large herds of swine follow corn-fed cattle and where little or no attention is given to food or shelter. A somewhat detailed description is given of an outbreak of a swine disease at Brookeville, Maryland. A bacteriological examination revealed the presence of *Bacillus coli-communis* and others of the same group. The author seems inclined to attribute the death of the animals to these organisms.

**Effects of tuberculin on tuberculous cows, F. L. RUSSELL** (*Maine Sta. Rpt. 1896, pp. 56-63*).—A record is given of experiments with tuberculin on tuberculous animals. Out of 116 tests made 33 reactions were obtained, leaving 83 failures. Why such results should be obtained does not appear. The amount of tuberculin used in making the injection was always uniform for the same stage of maturity. Animals so slightly diseased as not to be detected by a physical examination gave such widely different results that the author is forced to the conclusion that it is a matter of uncertainty whether a slightly diseased animal will react or not. A reaction may be obtained at one time and again a month later; or, a reaction may fail for as many as 3 years and then a very decided reaction may be obtained. That there is some law underlying the phenomena seems plain to the author, although he is not able to state what it is. Some animals, it is found, react repeatedly, while others do not, and the intervals between reactions vary from 2 days to more than a year. The author finds no grounds for supporting the theory that failure of tuberculous animals to react is due to an acquired tolerance of tuberculin. It is suggested "that the failure of tuberculin to cause reaction in tuberculous cows at times may be due to the fact that the disease is not making steady progress."

**Tuberculosis in the herd of dairy cattle at Aas Agricultural College, Norway, H. ISAACHSEN** (*Ber. Höjere Landbrugsskole Aas, 1895-96, pp. 84-86*).—Tuberculin tests made in June, 1895, showed that 113 head of cattle reacted out of 145 head in the herd (calves included),

or 78 per cent; 3 cases were suspicious; 85 per cent of 104 cows, two-year old or over, reacted; 75 per cent of 16 one to two year old heifers, and 52 per cent out of 25 calves less than a year old. The Ayrshire cows in the herd contained a larger proportion of diseased animals than the pure-bred domestic breeds, Telemark and Gudbrandsdal, or the crosses.—F. W. WOLL.

**A plant that poisons cattle**, U. P. HEDRICK (*Oregon Sta. Bul. 46*, pp. 12, pls. 1).—*Cicuta ragans*, which grows in the low pasture lands of Oregon, has been found to poison cattle in late winter and early spring. According to the author not less than 100 cattle in various parts of the State were poisoned last spring by this plant.

In an experiment in which the bulb was cut into small pieces and fed, along with carrots cut in the same way, to a 2-year-old heifer at 8 o'clock a. m., death resulted 1½ hours later. Upon post-mortem examination, pieces of the root were found in the rumen and in the second stomach. The lungs were highly congested, but otherwise nothing abnormal was noted. On the following day an experiment with a calf was made at 9.15 a. m., and an attempt made to counteract the effects of the poison by giving an ounce of turpentine in a quart of milk. The calf recovered its feet and tried to walk. Soon there were indications of spasms, and the dose of turpentine and milk was repeated, when the calf stood up until 11.30 a. m., then it went down as before. Aconite and milk were then given, and also a hypodermic injection of nitroglycerine, but the animal died at 11.45 a. m. From the beginning of the experiment there was a decided rise in temperature, the highest being to 106¼° F. Similar experiments were made later in the season (May), and it was learned that a much larger amount of the bulbs could then be consumed without serious effects. Hence the author concludes that cattle are likely to be poisoned only from the first of January to the middle of May. The simple remedies, such as old bacon grease, flour, and milk, recommended by stockmen in milder cases, the author thinks may be of some value, but that they will be unavailing with an animal that has swallowed even a very small quantity of the bulb when the poison is virulent. The best remedies are eradicating the plant from pastures or keeping cattle from lands where it grows.

**Report of the veterinarian**, A. T. PETERS (*Nebraska State Bd. Agr. Rpt. 1896*, pp. 191-216, pls. 7).—With the exception of a few tables, this is a reprint of Bulletin 47 of the Nebraska Station (E. S. R., 9, p. 93). A compiled popular account of glanders in its various forms is added.

**Contagious diseases of animals in Great Britain**, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896*, pp. 37-75).—This is a concise and critical account of the history of the struggles in Great Britain against swine fever, pleuropneumonia, tuberculosis, foot and mouth disease, and anthrax. The great disadvantage of leaving the diseases to independent local control, as was done in earlier times, is thoroughly brought out and compared with the advantages of control of repressive measures by a single central authority. The figures given by the author show a general decrease in the number of animals affected with the various diseases with the exception of swine fever. In the case of pleuropneumonia, for example, there were between 1870 and 1879 on an average 5,995 animals attacked per

annum, while during the succeeding decade the average per annum was only 2,017, and from 1890 to 1894, inclusive, there was an average of only 602 animals attacked.

**A report on rabies in Washington, D. C.,** V. A. MOORE and P. A. FISII (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 267-282, pls. 3*).—The method of inoculation for the diagnosis of rabies is described, a detailed account given of the cases received, and the pathology and etiology of the disease discussed. The difficulty if not impossibility of making a diagnosis of rabies in the street dog without the aid of inoculation is noted, as well as the fact that many dogs are supposed to be mad when they are not, and conversely, that many dogs not supposed to be mad die of rabies.

**Texas fever in Australia,** D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 85-95*).—An account is given of Texas fever in Australia, mostly compiled from the reports of C. J. Pound, director of the Queensland Stock Institute, of Brisbane. Among other things it is noted that Director Pound has found a protozoan parasite in the young cattle tick (*Ixodes boris*), which, although smaller, is believed to be identical with the parasite causing the fever, although no such parasite was found in the adult tick.

**Texas fever in Kansas** (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 318-321*).—The source traced to southern California.

**The detection of tuberculosis in cattle,** C. CURTICE (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 283-295, pls. 3*).—The various pieces of apparatus needed and the methods of using them are described, and the proper method of disposing of tuberculous cattle briefly set forth.

**The suppression and prevention of tuberculosis of cattle and its relation to human consumption,** J. NELSON (*Agr. Gaz. New South Wales, 8 (1897), No. 6, pp. 370-383*).

**Results of curative experiments on cattle affected with tuberculosis,** W. SAUNDERS (*Canada Expt. Farms Rpts. 1896, pp. 89-93*).—A record is given of the temperature results from injection of tuberculin, and also the details of some post-mortem examinations.

**Tuberculosis in swine, the nature of the disease, with a report of three cases,** V. A. MOORE (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 207-218, pls. 4*).—The occurrence of the disease in Europe is briefly noted; the source of infection, symptoms, diagnosis, morbid anatomy and the relation of swine tuberculosis to public health are discussed; and the 3 cases described.

**The communication of hog cholera by carrion crows,** T. S. FORD (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 325, 326*).—An account is given of an outbreak of this disease attributed to germs carried on the feet of carrion crows.

**An outbreak of cattle disease in Kansas** (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 322-325*).—Notes on a supposed outbreak of contagious pleuropneumonia—a false alarm.

**Ergotism in Kansas** (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 317, 318*).—An account of an outbreak at Selma, Kansas.

**An epidemic of purulent inflammation of the milk ducts, affecting seventy cows,** W. R. STOKES and A. W. CLEMENT (*Jour. Comp. Med., 1897, No. 3, pp. 135-138; abs. in Centbl. Bakt. u. Par., 1. Abt., 21 (1897), No. 22-23, p. 895*).

**How is calf fever to be prevented?** (*Landw. Wechubl. Schleswig-Holstein, 47 (1897), No. 37, p. 525*).

**Protective inoculation against swine erysipelas** (*Sächs. Landw. Ztschr., 45 (1897), No. 26, p. 310*).

**Protective vaccination against swine erysipelas,** LORENZ (*Braunsch. Landw. Ztg., 65 (1897), No. 36, p. 159*).

**The bacillus of the foot and mouth disease** (*Deut. Med. Wechuschr., 23 (1897), No. 8; abs. in Ztschr. Wiss. Mikros. u. Mikros. Technik., 14 (1897), No. 1, pp. 117, 118*).—A small bacillus always found measuring 0.5 to 0.9  $\mu$  long by from 0.3 to 0.1  $\mu$  thick. In hanging cultures somewhat motile. Stains well in watery anilins, best in car-

bofuehsin. Typical form appears in 24-hour cultures. Young bouillon cultures in brood oven show somewhat cocens-like forms. The longer forms— $0.9\mu$ —can be obtained on gelatin plates kept at  $20^{\circ}$ . Coli-like growth on media.

The status of the knowledge of the foot and mouth disease (*Deut. Landw. Presse, 24 (1897), No. 77, p. 708*).

Dipping cattle for the destruction of ticks, D. E. SALMON (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 109-118, pls. 3*).—This is compiled from a report by V. A. Nørgaard and sets forth the various points to be taken into consideration in performing experiments for determining the proper disinfectant and the strengths of the same to be employed in disinfecting cattle.

Aside from glycerin, the best of all remedies as a dip, but which is too expensive for practical purposes, there are 2 coal-tar preparations, chloro-naphtholenn and The Lone Star Cattle and Sheep Wash. The former is readily soluble in soft water and works well in a 2 per cent solution. In a trial test 40 cows, all very ticky, were dipped; 24 hours later the smaller ticks were all dead and also many of the fully gorged ones. On the day following the ticks still living were found to be soft, wrinkled, and of a yellow mottled appearance, and 2 days later were all found to be dead. The same solution was used on 300 head of cattle, many of which were calves less than a year old, and all seemed to endure the dipping without becoming stiff and with only a slight peeling off of the epidermis between the hind legs and on the sides of the neck. Chloro-naphtholenn seems to retain its tick-destroying properties considerably longer than the Lone Star Wash.

The effect of dipping solutions on cattle is described.

Laws of States and Territories for the control of contagious animal diseases (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 333-355*).—Text of the laws of Alabama, Arizona, Kentucky, Massachusetts, Montana, New Jersey, New Mexico, North Dakota, and Pennsylvania.

Transactions of the Bureau of Animal Industry for 1895 and 1896 (*U. S. Dept. Agr., Bureau of Animal Industry Rpts. 1895 and 1896, pp. 5-35*).—An account of the transactions of the Bureau for the years 1895 and 1896, with recommendations for legislation.

## TECHNOLOGY.

The control of the temperature in wine fermentation, A. P. HAYNE (*California Sta. Bul. 117, pp. 19*).—The factors contributing to rise of temperature in fermenting musts and the means of controlling the temperature are discussed. Wine yeast requires a comparatively low temperature for its normal development and the production of the best wine. A temperature of about  $100^{\circ}$  F. stops yeast fermentation and at the same time accelerates the growth of various harmful bacteria. The initial temperature of the grapes is higher in California than in many wine-producing regions of Europe; the California musts as a rule have a high sugar and a low acid content, and there is a tendency in California to use very large fermenting tanks. All these peculiarities make necessary some means of cooling the musts.

Descriptions and illustrations are given of a French apparatus for cooling must, of the apparatus used by the station, and also of a modified form of the one used. With the French apparatus the must is pumped through about 500 feet of  $1\frac{1}{2}$ -in. round tubing, arranged in 2 columns. The tubes are kept cool by the constant dripping of water upon them from a tank above. With the apparatus used by the station the must was forced through a column of tubes having a total

length of only 43 ft. Flat tubes 4 by 1½ in. were used. They were kept cool by a fine spray of water carried by a strong blast of air. The evaporation taking place under these conditions added greatly to the cooling effect of the apparatus. It was found that one man could pump from 1,000 to 1,400 gal. per hour and that in passing through the cooling apparatus at that rate the must was cooled from 10 to 13° F.

**Preservation of grape juice**, J. CRAIG (*Canada Expt. Farms Rpts. 1896*, pp. 165-168).—The process of preparing unfermented grape juice is described and 16 experiments on the preservation of the juice are reported. The results indicate "that the natural flavor of the grape juice may be preserved intact by raising the temperature of the juice gradually to 170° F., keeping it at this point for 10 minutes, and then quickly bottling it, taking care to use absolutely air tight and thoroughly sterilized vessels. . . . The addition of sugar in the proportion of 4 oz. to each quart of liquid will improve the quality and palatability of the juice of the more acid varieties of grapes. . . . The use of antiseptics such as salicylic acid should not be encouraged."

**The canning industry**, J. CRAIG (*Canada Expt. Farms Rpts. 1896*, pp. 164, 165).—A note is given on the extent of the canning industry in Canada. The varieties of fruits and vegetables preferred by canners are given in tabular form, being arranged according to their popularity.

**The manufacture of potato starch**, O. SAARE (*Die Fabrikation der Kartoffelstärke. Berlin: J. Springer, 1897*, pp. XII, 577, ill.).

**"Malton wine"** and its examination, SCHILLER and TIETZ (*Forsch. Ber. Lebensmtl., 4 (1897)*, No. 12, pp. 354-361).

**Pure yeasts in wine making**, H. BECKER (*Centbl. Bakt. u. Par., 2. Abt., 3 (1897)*, No. 23-24, pp. 667-671).

**On the use of pure yeasts in wine making**, J. BEHRENS (*Centbl. Bakt. u. Par., 2. Abt., 3 (1897)*, No. 23-24, pp. 671-674).

**On the acarids of wine of grevache** (*Carpoglyphus passularum*), E. L. TROUÉ-START (*Compt. Rend. Acad. Sci. Paris, 125 (1897)*, No. 6, pp. 363-365).—On *Carpoglyphus (Acarus) passularum*. The quality of the wine, it is asserted, does not seem to be affected by the presence of the mites. They are readily killed by exposure to light. They attack raisins, and it is through the use of these in wine making that they find entrance to wines.

**The examination of certain distilled liquors** (*Edelbranntwein*), K. AMTHOR and J. ZINK (*Forsch. Ber. Lebensmtl., 4 (1897)*, No. 12, pp. 362-373).

**A study of the rancidity of olive oil**, A. LOIR and R. MOULINE (*Bul. Dir. Agr et Com., 12 (1897)*, No. 5, pp. 293-296, pl. 1).

## AGRICULTURAL ENGINEERING.

**Is electrotechnics adapted to agricultural uses?** C. KÖTTGEN (*Landw. Jahrb., 26 (1897) No. 4-5*, pp. 637-691, pls. 15, figs. 6).—The subject is discussed both from the technical and the agricultural side. The conclusion is reached that electrotechnics must make many advances before it is perfectly adapted to agricultural uses. Electricity offers a power easily applied over an extended area and requiring relatively light and easily transportable machinery.

The most favorable conditions for the use of electric power are water

power or steam from some other industry for generation of electricity, and complete and uniform utilization of the electricity from a large central plant.

Electric motors are better adapted to plowing than to any other farm operation. They may, however, be applied with advantage to threshing, feed cutting, irrigation, drainage, lighting, etc.

Experiments have shown that the use of electricity for driving farm machines, especially plows, is technically practicable, but its economy is questionable on a farm of less than 600 acres.

Electric plows are about as expensive as steam plows, if the electric plant is used for no other purpose, but they possess the advantage of greater lightness, which better fits them for hilly and soft ground.

An important advantage resulting from the use of motor plows is the improvement of the tilth of the soil and the consequent increase of yield.

Numerous estimates of the cost of producing and applying electricity under different conditions are given.

**Irrigation near Greeley, Colorado,** D. BOYD (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 9, pp. 90, pls. 21, figs. 8*).—In this paper no attempt is made to describe the details of the development of agriculture or of the system of water control in this colony, but simply “to present the more prominent facts and those of most interest and value to the citizens of the West who are now following in similar paths and seeking to lay the foundations for broad and lasting systems of water utilization and control by which the rights of all may be determined and protected.” The report is prefaced by an introduction compiled from the records of the Geological Survey and from other sources, to illustrate the climatic and topographic conditions of Cache la Poudre Valley, in which Greeley is situated, and also the limitations of water supply, and discusses the following subjects: Settlement in Cache la Poudre Valley, canal and reservoir systems, conservation of water supply, legislative and judicial control of water, construction and operation of canals, agricultural practice, and underground waters.

**Underground waters of southwestern Kansas,** E. HAWORTH (*Water Supply and Irrig. Papers, U. S. Geol. Survey, No. 6, pp. 65, pls. 12, figs. 2*).—This is a summary of results of fieldwork carried on during the summer of 1896 with a view to obtaining “detailed information concerning the amount and quality of the underground waters in order to throw light upon the problems connected with the utilization of these in the development of agriculture upon the Great Plains.”

“The area discussed in this report is located in southwestern Kansas and covers 1 degree each of latitude and longitude. It is bounded on the east by the one hundredth meridian west of Greenwich, on the west by the one hundred and first meridian, on the south by the thirty-seventh parallel, and on the north by the thirty-eighth. . . . [The author concludes] that the amount of ground water under the area here described is sufficient to meet any demands that will likely be made upon it, even should industries spring up in the West which will use many times as much

water as now seems probable. The greatest needs for western Kansas now, and for the whole plains area, are better methods of raising water from beneath the surface, and better methods in using it."

**Report of the irrigation engineer, S. FORTIER** (*Utah Sta. Rpt. 1897, pp. 38-50*).—This report is devoted mainly to a summary of work on the water supply of the Cache Valley, previously published in detail in Bulletin 50 of the station (E. S. R., 9, p. 427).

**New fittings of the cow stable, G. M. GOWELL** (*Maine Sta. Rpt. 1896, pp. 22-27, pl. 1, fig. 1*).—The plan and detailed construction of the cow stalls in the station barn are given, with brief notes on lighting and ventilating and a description of a fastening devised for use in bull pens. In the construction of the improved cow stalls the leading features of the "Hoard stalls" were adopted.

## STATISTICS—MISCELLANEOUS.

**Tenth Annual Report of Georgia Station, 1897** (*Georgia Sta. Rpt. 1897, pp. 130-136*).—An account of the operations of the station for the year ending December 31, 1897, with notes on the station organization, mailing list, building and repairs, publications, etc.; and the usual statement of receipts and expenditures for the fiscal year ending June 30, 1897.

**Reports of director and treasurer of Maine Station, 1896** (*Maine Sta. Rpt. 1896, pp. 1-21*).—Includes a financial statement for the fiscal year ending June 30, 1896, lists of acknowledgments and of available station reports, with brief abstracts of the same; and a report by the director on the personnel of the station and the different lines of work carried on during the year.

**Reports of director and treasurer of Pennsylvania Station, 1896** (*Pennsylvania Sta. Rpt. 1896, pp. 3-17, 247-250*).—Treasurer's report for the fiscal year ending June 30, 1896; report of the director reviewing the work carried on at the station during the year; and lists of station exchanges and publications. The financial support given to the station by the State since 1887 is noted and compared with similar data for other States.

**Eighth Annual Report of Utah Station, 1897** (*Utah Sta. Rpt. 1897, pp. 66*).—A report by the director on the reorganization of the station staff, the present status of the station, work of the different departments during the year, station improvements, mailing list, publications, etc.; reports by the heads of departments, parts of which are noted elsewhere; and a financial statement for the fiscal year ending June 30, 1897.

**Reports of director and treasurer of Vermont Station** (*Vermont Sta. Rpt. 1896-'97, pp. 1-27*).—These reports cover the 18 months ending June 30, 1897. An announcement is given as to the purpose of the station and the general scope of the work which it is prepared to undertake. The director's report gives a detailed review of the work of the various departments; notes on the personnel, equipment, mailing list, etc.; and a subject list of the bulletins and reports of the station now in print. Brief summaries of Bulletins 50-59 of the station are appended.

**Fifth Annual Report of West Virginia Station, 1892** (*West Virginia Sta. Rpt. 1892, pp. 56*).—A general review of the work of the station for the year, by the director, with more detailed reports by the chemist, agriculturist, entomologist, botanist and microscopist, and treasurer; and a report relative to fruit and nut trees now being tested at Charlestown by W. W. Brown. The report of the chemist is noted in detail elsewhere (see p. 807).

**Sixth Annual Report of West Virginia Station, 1893** (*West Virginia Sta. Rpt. 1893, pp. 68*).—A report by the director on the general conduct and operations of the station in its various departments during the year, with recommendations, notes on publications, etc.; and somewhat more detailed reports by the chemist, entomologist, agriculturist, and horticulturist on the work of their respective

## NOTES.

---

ARIZONA STATION.—A. J. McClatchie, M. A., has been appointed agriculturist and horticulturist of the station, and located at Phoenix, Arizona.

COLORADO STATION.—Harvey H. Griffin, B. S., has been appointed to succeed W. Frank Crowley as superintendent of the Arkansas Valley Substation, at Rockyford, Colorado.

IDAHO STATION.—W. L. Payne, of Moscow, has been elected treasurer of the station to succeed P. A. Reagan, resigned.

MONTANA COLLEGE AND STATION.—Frank Beach, professor of irrigation engineering and agriculture in the college and agriculturist of the station, has resigned, to take effect April 1, 1898.

NEBRASKA UNIVERSITY AND STATION.—F. W. Card, professor of horticulture in the university and horticulturist of the station, has resigned, to take effect September 1, 1898, and has accepted a similar position in the Rhode Island Agricultural College and Experiment Station.

OKLAHOMA STATION.—There has been a marked increase during the past few months in the applications for the bulletins of this station and in the correspondence requesting information on specific points. The station has completed one stage of an experiment contrasting the value of Kafir corn meal and Indian corn meal as food for steers. In this trial the steers on Kafir corn meal ate more and made better gains than those of like quality fed Indian corn meal.

# EXPERIMENT STATION RECORD.

VOL. IX.

No. 10.

The act of Congress making appropriation for this Department for the fiscal year ending June 30, 1899, carries the following general items: Office of the Secretary, \$84,300; Weather Bureau, \$937,502; Bureau of Animal Industry, \$983,440, with \$37,500 for printing seventy-five thousand copies of the Special Report on the Diseases of the Horse, one-third for the use of the Senate and two-thirds for the use of the House; Agricultural Experiment Stations, \$760,000; Division of Statistics, \$140,160, including \$10,000 for the investigations on foreign markets; Division of Botany, \$28,800; Division of Forestry, \$28,520; Division of Agrostology, \$18,100; Division of Vegetable Physiology and Pathology, \$26,500; Division of Pomology, \$16,000; Division of Biological Survey, \$27,560; Division of Entomology, \$29,500; Division of Chemistry, \$29,500, \$7,500 of which, as heretofore, is for investigating the adulteration of foods, drugs, and liquors; Division of Soils, \$16,300; Nutrition Investigations, \$15,000; Public Road Inquiries, \$8,000; Division of Seeds, \$130,000; Division of Publications, \$85,260, of which \$35,000 is for the preparation and printing of Farmers' Bulletins; Division of Accounts and Disbursements, \$16,300; Library, \$12,960; Experimental Gardens and Grounds, \$22,500; Domestic Sugar Production, \$7,000; Irrigation Information, \$10,000; Museum, \$2,500; furniture, cases, repairs, and postage, \$11,000; and contingent expenses, \$25,000.

The total amount of the appropriation is \$3,509,202, an increase of \$326,300 over the appropriation for the year ending June 30, 1898. The principal increases are for the Weather Bureau and the Bureau of Animal Industry. The Weather Bureau appropriation is increased \$53,800, and provision made for the establishment of 16 additional stations and the erection of a small building on the Government reservation at Sault Sainte Marie. There is an increase of \$228,200 for the Bureau of Animal Industry for extending the work of inspection and of combating animal diseases, making the appropriation for these purposes \$900,000. Hog cholera is mentioned as one of the diseases which may receive attention, and the expenditure of \$50,000 is authorized, \$25,000 of which is to be immediately available, "for making and using serum for the prevention and cure of hog cholera."

A notable feature of the appropriation for seed distribution is the setting aside of \$20,000 for the introduction from foreign countries of

seeds, bulbs, trees, shrubs, vines, cuttings, and plants to be used for experimental tests in cooperation with the agricultural experiment stations. This feature is to be in charge of Mr. D. G. Fairechild.

The appropriation for experiment stations includes the usual \$30,000 for the Office of Experiment Stations, and \$10,000 for agricultural investigation in Alaska, an increase of \$5,000. The Alaska work will remain under the supervision of this Office and will be under the immediate charge of Prof. C. C. Georgeson, formerly of the Kansas Experiment Station, who went to Alaska about the middle of April.

The provision for collecting information on irrigation is new and is on a different basis from former appropriations. It is "for the purpose of collecting from the agricultural colleges, agricultural experiment stations, and other sources, including the employment of practical agents, valuable information and data on the subject of irrigation, and publishing the same in bulletin form." This should furnish a basis for procuring data on the strictly agricultural side of irrigation, *i. e.*, the application of irrigation, which, as well as the engineering side, presents a multitude of problems for profitable investigation.

The investigation of domestic sugar production is revived by an appropriation of \$7,000 "to enable the Secretary of Agriculture to continue inquiry and ascertain the progress made in the production of domestic sugar from beets and sorghum, including the area of available lands adapted thereto by irrigation or otherwise, and to investigate all other matters concerning the same."

The appropriation for the Division of Botany is increased \$5,000 over the previous year, and a new provision made for seed inspection. This authorizes the purchase of samples of seeds in the open market for testing, and, in case they are not found to be up to the standard, the publication of the results of the tests, with the names of the seedsmen.

The amount specified for the Division of Publications does not include the available funds for printing the miscellaneous publications of the Department. This is provided for in a separate appropriation of \$85,000, which is a part of the general appropriation for printing.

It will be seen that provision is made for the extension of the work of the Department in several directions. The advantages offered by the experiment stations for supplementing and cooperating in the work of the National Department are more fully recognized in the appropriation act than ever before. To the former provision for cooperation in the study of matters related to human nutrition is now added the testing of foreign introductions, which it is hoped will stimulate investigation on the improvement of agricultural and horticultural plants in general, and studies on the management and use of irrigation. Working hand in hand, the Department and the stations are of great mutual assistance to one another and form a combination for the investigation and promotion of agriculture which is unsurpassed.

# ORIGIN AND FORMATION OF ORGANIC MATTER IN PLANTS.

P. P. DEHÉRAIN,

*Member of the Institute of France.*

By the ordinary method of sand culture, in which the plant is grown in sand free from organic matter, it may be demonstrated that the plant accumulates considerable quantities of carbon and nitrogen during its growth. This carbon and nitrogen with the elements of water form the organic constituents of the plants, which with a small quantity of mineral ingredients make up the roots, stem, and leaves and give the seed its valuable nutritive qualities. Since the soil did not contain either carbon or nitrogen, the plant must have drawn these two elements from the air. It is the purpose of this article to explain the nature of this fixation of the carbon and nitrogen of the air.

## ORIGIN OF THE CARBON OF PLANTS.

The classic experiments of Priestley, in 1771, established the fact that plants exhale oxygen. Later researches made by Ingenhous and by Tenneber explained the decomposition of the carbon dioxide of the air and the evolution of oxygen by the leaves under the influence of light. The experimental demonstration of this decomposition is easily made by the method of Cloez and Gratiolet as follows:

Introduce in a liter bottle of white glass 200 cc. of water saturated with carbon dioxide. Fill the bottle with ordinary water and immerse in the liquid branches of such marsh plants as *Elodea canadensis*, *Ceratophyllum submersum*, or *Potamogeton crispus*. Close the bottle with a rubber stopper provided with a tube for drawing off the gas evolved and place in the sunlight. After a few hours a considerable amount of gas is obtained which is rich in oxygen. The green plants therefore draw their carbon from the carbon dioxide and it is important to understand the process by which this is done.

## PENETRATION OF THE CARBON DIOXIDE INTO THE LEAVES.

The earth's atmosphere contains only 3 parts of carbon dioxide in 10,000 of air. It is evident, therefore, that in order that plants may obtain the carbon which they require from a medium so poorly supplied with it rapidity of absorption by the tissues must compensate for the scarcity of the element in the air.

In the first place the absorption of carbon dioxide is favored by the form of the leaves, which is such that they offer, as compared with their weight, an enormous absorbing surface. In a tree the leaves are at the

extremities of infinitely ramified, flexible branches, which are agitated by the slightest breeze, thus facilitating contact of the leaves with the constantly renewed layers of air about them. That the absorption of carbon dioxid is very rapid, may be shown by placing a leaf from which the air has been exhausted by means of an air pump in an atmosphere of carbon dioxid in an apparatus<sup>1</sup> which measures the change of the volume. It will be observed that absorption begins instantly, but that it is largely dependent upon the quantity of the water present in the leaf. Thus, the coefficient of absorption of the carbon dioxid in old leaves of Japanese Euonymus, containing 66.3 per cent of water, was found to be 0.70 at 15°, while in young leaves of the same tree containing 75.4 per cent of water the coefficient was 0.83. A comparison, at different temperatures, of the coefficient of absorption of carbon dioxid in the leaves with that in pure water, shows the absorption in the leaves to be somewhat greater than in pure water. This indicates that the carbon dioxid is not simply dissolved in the water in leaves, but that it combines with the water to form a hydrate. It will be shown later that this fact is of great importance.

If a section of the epidermis of a leaf be examined under the microscope, numerous little openings (stomata) will be observed which are generally more abundant on the under side than on the upper side, which is usually covered with a thick, smooth, glossy cuticle. The experiments of Boussingault led to the conclusion, which was long accepted, that the carbon dioxid diffused through the cuticle. F. Blackman<sup>2</sup> has recently demonstrated, however, that the carbon dioxid enters primarily through the stomata.

#### DECOMPOSITION OF CARBON DIOXID IN LEAVES.

The carbon dioxid which is absorbed by the leaves is decomposed and the products of this decomposition are utilized in the formation of the simplest primary organic compounds, from which the more complex constituents of plants are derived. To accomplish this the principal condition is that the leaf be perfectly healthy. If it does not contain its normal proportion of water, *i. e.*, if the roots do not draw from the soil as much water as is given off through the leaves, the decomposition of carbon dioxid is checked. Assimilation has ceased when as at the end of a summer day the leaves of the tobacco plant, for instance, are hanging down the stem, or those of the beet lie flat on the soil. In fact it has been found that the decomposition of carbon dioxid begins to decline even before the leaves have lost their turgescence.

Light is absolutely essential to the assimilation of carbon by the leaves of plants. The principal source of this energy is, of course, the sun, but attempts have been made to utilize artificial light, especially

<sup>2</sup> *Proc. Roy. Soc. [London]*, 57 (1895), p. 165; *Phil. Trans. Roy. Soc. [London]*, 186 (1895), p. 48 (E. S. R., 6, p. 782).

the electric light for forcing plants. Siemens in England, Bailey in America, and the author in France have made experiments of this character. Since there is no doubt that with the increasing use of water power for the production of electricity, a large supply of electric light can be economically obtained, it is highly interesting to learn what its action is on plants. All observers have found that rays from an arc lamp without a globe exert an injurious influence, blackening the epidermis of the leaves. During the author's experiments in 1881 the epidermis exposed to the direct rays became black, while the parts protected by the upper leaves preserved their beautiful green color. The line of demarcation was as sharp as in a photographic plate. The injurious influence ceased as soon as the lamp was surrounded by a white glass globe through which the ultra-violet rays passed with difficulty. To understand the influence which the heat rays situated at the other extremity of the spectrum exert on vegetation, we must recall to mind that in respiration leaves, like all other plant organs, absorb oxygen and exhale carbon dioxide, a process which is precisely the opposite of that which occurs in assimilation.

It must also be remembered that the activity of respiration increases with elevation of temperature, while rise in temperature has only a very slight effect on assimilation. Maquenne and the author<sup>1</sup> some years ago made a careful study of the action of both light and heat rays on leaves. In this research two sources of light were used, the Drummond light, which is obtained by rendering a piece of quicklime incandescent by means of the oxyhydrogen blowpipe, and the Bourbouze lamp, which is composed of a cylinder of platinum wire gauze, which becomes incandescent when heated with illuminating gas, the combustion of which is promoted by a strong current of air. The leaves were introduced into tubes containing an atmosphere of known composition and were placed very near the lights, but were protected by screens containing transparent liquids of varying diathermanous properties. In some cases water was used, which allowed the light rays to pass but retained the heat rays. In other cases the screens were filled with benzine or with chloroform, which are also transparent but much more diathermanous than water. Exposing the leaves to the action of the Drummond light, which is poor in heat rays, and surrounding them with a screen filled with water promoted reduction, the proportion of carbon dioxide in the tube diminishing, while the oxygen increased. When the screens were filled with chloroform, however, and the Bourbouze lamp was used, which is rich in heat rays, the opposite effect was obtained, *i. e.*, the carbon dioxide increased and the oxygen diminished. In this case the phenomena of respiration took the place of those of assimilation.

Passing from the study of the chemical and heat rays to that of the light rays in the central part of the spectrum, we find that the latter

<sup>1</sup> Ann. Agron., 5 (1879), p. 401.

produce very different effects from the former. Draper demonstrated long ago that the orange rays are the most active in decomposing carbonic acid in the leaves. This conclusion was fully confirmed by the researches of Sachs, Cailletet, and of the author made nearly 30 years ago. The reasons for this special action of the rays of this part of the spectrum were not investigated until the Russian physiologist, Timiriazeff, took up the subject. He found that the rays which are most active in decomposing carbon dioxid are the orange and yellow, which are absorbed by chlorophyll when the latter is examined with the spectroscope. The same fact has been beautifully demonstrated by Engelmann. He received a ray of light upon a prism so placed under the objective of a microscope that on looking through the instrument the different rays of the spectrum could be seen. He then put a drop of water on a slide and added a filament of green alga and some putrefactive bacteria, which were aerobic. It was observed that the bacteria congregated in great numbers on that part of the alga lighted by the yellow and orange rays. In the green region only a few were observed and these finally collected in the blue portion. In other words, the bacteria collected in the different rays in numbers approximately proportionate to their activity in assisting the decomposition of the carbon dioxid by chlorophyll.

Evidently the rays which pass freely through the chlorophyll exert no action. So it happens, as shown above, that the extreme red or the green rays are without effect on the decomposition of carbon dioxid. On the other hand, the orange and blue rays are retained and absorbed by the chlorophyll, and thus made available for the work of decomposing carbon dioxid. The fact that orange rays are much more effective than the blue is easily explained. The decomposition of the carbon dioxid, with the evolution of oxygen, requires an expenditure of energy equal to that involved in the burning of carbon in oxygen. In order, therefore, that the rays may be effective for reducing carbon dioxid they must be not only readily absorbed but sufficiently warm. The orange rays, which are situated at the side of the spectrum where the heat rays are concentrated, are far more energetic than the blue because, in addition to being readily absorbed, they are warmer than the latter.

The decomposition of carbon dioxid can only be brought about by the aid of outside energy. This energy is supplied by the sun's rays. Since decomposition of carbon dioxid in the chlorophyll cells is the source of the organic constituents of plants, and since these substances are essential to the life of animals, we see that all living beings on the earth's surface owe their activity primarily to the sun.

#### PRODUCTION OF CARBON COMPOUNDS BY DECOMPOSITION OF CARBON DIOXID.

It does not suffice to know that the leaves, saturated with water, absorb the carbon dioxid of the air and under the influence of the sun's rays evolve oxygen. It is necessary to define this process and

to explain how organic matter is derived from the product of this decomposition.

Boussingault demonstrated that when one volume of carbon dioxid is decomposed by the leaves under the influence of sunlight one volume of oxygen results; that is, precisely the amount contained in one volume of carbonic anhydrid.

Maquenne and the author, in the article already referred to, report the result of studies on the quantities of carbon dioxid absorbed by leaves, taking into account also the quantities which would be absorbed by a volume of water equal to that contained in the leaves under experiment. The results, as already stated, indicated that the absorption is not simple solution of carbonic anhydrid in the water of the leaves, but a chemical combination of the carbon dioxid with water to form the acid  $\text{CH}_2\text{O}_3$ . This carbon dioxid decomposes in the leaves, giving off a volume of oxygen ( $\text{O}_2$ ) equal to that of the carbonic anhydrid absorbed as observed by Boussingault, and leaving a residue of formic aldehyde ( $\text{CH}_2\text{O}$ ). The fact that formic aldehyde has never been found in plants might be taken as casting doubt upon the correctness of the above hypothesis, but the hypothesis is strengthened by the fact that the molecules of this aldehyde combine easily with each other; and although we do not find formic aldehyde itself we may safely assume that some at least of the bodies present are the result of combinations of molecules of formic aldehyde. As a matter of fact bodies which might be thus formed are extremely abundant in the vegetable kingdom, as will be seen hereafter. It is known also that the aldehydes combine readily with oxygen and hydrogen and it is of great interest to ascertain whether there are not present in plants some products thus derived from formic aldehyde. As a matter of fact such substances have been found. By oxidation formic aldehyde yields formic acid, which gives to nettles their irritating properties. The addition of hydrogen to formic aldehyde in proper proportions yields methyl alcohol, which Maquenne found in all the plants which he studied.

While the presence in plants of these two compounds so closely allied to formic aldehyde supports the hypothesis of the formation of this aldehyde in the chlorophyll cells at the moment of the decomposition of the carbon dioxid by the sun's rays, there are other proofs of a more convincing nature. The reducing sugars are widely distributed in plants. Loew, and later Fischer, starting with formic aldehyde, have prepared these sugars artificially. They succeeded in linking together six formic aldehyde molecules, and thus formed a reducing sugar resembling those found in plants. This beautiful synthesis convinced the physiologists that the primary organic compound from which all the others are derived is formic aldehyde produced by the decomposition of the hydrated carbon dioxid. Many other compounds common in plants are formed by the combination of molecules of formic aldehyde, such as glycerin, which exists in all oils and which contains three molecules of formic aldehyde combined with hydrogen; the gums, which

readily yield a sugar containing five molecules of formic aldehyde, and persite, found in the fruit of the alligator pear, which contains seven molecules of the aldehyde.

Starch is easily transformed into glucose by simply heating the starch with weak acid solution. This in fact is the method employed in the commercial preparation of glucose. Starch is also transformed into glucose during germination by the action of a ferment present in the seed. This change is so easy and so frequent that there is no doubt that the transformation could be reversed; that is, the glucose could be changed into starch. Up to the present time, however, this has not been done by purely chemical means, but when leaves are placed in a solution of glucose starch soon appears in them. The starch is formed from the glucose through the combination of several molecules of the latter, water being eliminated.

Starch is very abundant in leaves which have been exposed to sunlight. Its presence is more easily detected than that of glucose. The latter is but a transition stage, while the starch is reserve material which remains in the tissues much longer than glucose.

The starch which is so abundant at the end of the day disappears during the night. The leaf is thus seen to be both a laboratory and a storehouse which is continually emptying and filling itself. The starch disappears from the leaves in the form of glucose. Adult plants utilize this transfer form of starch in the formation of cellulose, just as young plantlets utilize the glucose formed from starch in the cotyledons of the seed during germination.

The different steps have now been traced in the formation of the organic matter of plants from the simple carbon dioxide absorbed to the complex carbohydrates of the plant tissues. It now only remains to briefly discuss the derivation of some particular forms of these carbohydrates. Among the most important of these is cellulose, which forms the envelope of the cells and which is easily changed into reducing sugars under the action of acids. It appears during the germination of seeds simultaneously with the disappearance of starch. There is little doubt that it is derived from glucose and consequently from formic aldehyde. It seems clear, therefore, that all the carbohydrates, the gums, sugars, starch, inulin, and cellulose originate in the activity of the chlorophyll cells. The same is probably true of the tannin and resin groups. There are, however, certain plants which contain a group of sugars known as the inosites which are true carbohydrates, but whose molecular construction is different from that of the other glucoses, since their derivatives belong to the aromatic series and not to the fatty acid series to which the other groups belong.

There is one other important point which needs some explanation. If we study the phenomena of assimilation in a leaf which has been exposed to sunlight, we will find that the volume of oxygen evolved equals that of the carbonic acid decomposed. The plant utilizes the

carbon, but the proportion of oxygen which it contains remains unchanged. This is not true, however, when we determine the changes in composition which the air in which a plant is living undergoes. Schloesing found that under such conditions the volume of oxygen evolved was larger than the volume of carbon dioxide absorbed. This indicates that the evolution of oxygen is not due simply to decomposition of carbon dioxide. Doubtless the greater part of this excess of oxygen is due to reduction of nitrates which the plants take up from the soil, but, as is shown below, a study of plant respiration reveals another source of oxygen.

PLANT RESPIRATION—THE FORMATION OF SUBSTANCES RICH OR POOR IN OXYGEN—FATTY SUBSTANCES, RESINS, AND VEGETABLE ACIDS.

By the term respiration we understand the phenomena of the absorption of oxygen and the evolution of carbon dioxide. Respiration occurs in all plant organs and is a function of such importance that when interfered with by the exclusion of oxygen the death of the plant results. If the roots, buds, moistened seeds, and branches of a plant be placed in a flask and a current of air free from carbon dioxide be passed over them and then led through a solution of barium hydrate, the latter will become milky, due to the formation of barium carbonate, thus showing that the vegetable matter has evolved carbon dioxide. The leaves throw off carbon dioxide except when they are exposed to the light and respiration is masked by assimilation. During the night or in dense shade they throw off carbon dioxide. When the relation between the oxygen absorbed and the carbon dioxide evolved is carefully determined, it is found that this relation is considerably modified by the temperature to which the leaves are exposed. In a low temperature the oxygen absorbed is usually greater than the carbon dioxide evolved, while in a high temperature the reverse is true, that is, there is more carbon dioxide evolved than oxygen absorbed. Since one volume of carbon dioxide contains exactly one volume of oxygen it is evident that when the volume of carbon dioxide evolved is greater than the oxygen absorbed the plant is losing oxygen. This explains how the glucoses which are found in the pods of colza are transformed into the fatty substances of the seed and how inosite and its derivatives formed by chlorophyll action in caoutchouc trees give a resin which is devoid of oxygen. The nature of this transformation has not yet been explained, but the above observations indicate that these substances, like starch, cellulose, and sugar, are derived from formic aldehyde, which, as already explained, is assumed to be the primary substance from which all plant substances are built up.

The formation of acids in plant tissues is explained more easily than that of fatty substances and resins. When starch or sugars are subjected to the action of dilute nitric acid, oxalic acid is produced. Simi-

lar treatment of other saccharine bodies results in the production of tartaric acid. Plant acids are due to a partial oxidation of neutral substances. When the carbohydrates oxidize at a low temperature or the penetration of oxygen into the tissues of the plant is interfered with by the structure of the organs, combustion of the neutral substances is not complete, *i. e.*, they are not reduced to carbon dioxide and water. In this case the oxygen combines with the substances to produce the acids. For example, considerable amounts of oxalic acids and oxalates are found in the juice of the cactus, especially the prickly pear, which is but slightly permeable to air. When, therefore, the volume of oxygen absorbed is greater than the volume of carbon dioxide evolved it may be assumed that oxygen has been fixed by organic compounds in the plant to produce acids. These acids, then, are derived from neutral substances by oxidation, and, consequently, trace their ultimate origin to the decomposition of the carbon dioxide in the chlorophyll cells.

#### ORIGIN OF THE NITROGEN IN PLANTS.

##### ORIGIN OF THE NITROGEN IN LEGUMINOSÆ.

In the experiment to which attention was called at the beginning of this article it would have been impossible to grow peas without adding a few cubic centimeters of an infusion of fertile soil to the sand. If this precaution were not observed with the peas or if the seed of some nonleguminous plant were used the experiment would be a failure. The seed would produce a sickly plant which would soon die of starvation due to the absence of one of the elements—nitrogen—necessary to its development. Although the leaves of plants grow in an atmosphere four-fifths of which is nitrogen they are entirely incapable of directly utilizing this element.

The process by which the free nitrogen of the atmosphere is utilized by plants has only been explained in comparatively recent years. Hellriegel and Wilfarth in 1886 reported experiments which demonstrated the ability of Leguminosæ to attain normal development in soil absolutely deprived of organic matter, the only precaution necessary being the addition of a small amount of an infusion of fertile soil. A few weeks after the addition of the infusion the roots of the leguminous plants were covered with tubercles which microscopic examination showed to be filled with micro-organisms. Bréal has shown that inoculations may readily be made with these organisms by pricking a tubercle with a needle and then inserting it into a growing root.

The tubercle bacteria have been cultivated and their products have recently been brought into commerce under the name of "Nitragin," which is used for supplying these organisms to soils which are deficient in them. The growth of leguminous plants in sterile sand depends upon the presence on their roots of tubercles filled with these organisms. Through their agency the plant is supplied with nitrogen for

the production of nitrogenous matter, so that if the mineral elements are present in sufficient quantity the plant makes normal growth. The plant profits by the nitrogen furnished by the bacteria while the latter utilize the carbonaceous matter supplied by the plant, thus establishing a symbiosis. Although the process of fixation of nitrogen by the organisms and its utilization by the plant has not yet been clearly explained, we can understand how that, notwithstanding the great quantities of nitrogen carried away from the soil with every cutting of alfalfa or clover, the amount of nitrogen in the soil increases rather than decreases.

#### ORIGIN OF THE NITROGEN OF NONLEGUMINOUS PLANTS.

It has been shown by numerous analyses that soils abandoned for centuries to natural vegetation in which grasses predominate are quite rich in nitrogen. There are mountain meadows in France which during the open season are grazed by milch cows, and although this involves the removal of a considerable amount of nitrogen, and no fertilizers are used, these soils constantly increase in nitrogen content. While soils which are continuously cultivated frequently contain not more than  $1\frac{1}{2}$  to 2 parts per thousand of combined nitrogen, permanent meadows contain 5, 7, 9, and even 10 parts per thousand. The prairies of Western America are also well-stocked with nitrogen. It is interesting to trace the origin of this nitrogen.

Although the investigations of Ville and Atwater and those at Rothamsted and Grignon had proved that free nitrogen intervenes in the phenomena of vegetation, the process of fixation of nitrogen in the soil was not understood until explained by Berthelot, who showed that nitrogen is fixed in the soil by bacteria. Winogradsky cultivated certain of these bacteria in sugar solution and found that they decomposed the solution, forming butyric and acetic acids and evolving carbon dioxide and hydrogen. They are therefore very similar to if not identical with the organisms studied by Maquenne and the author in 1882<sup>1</sup> and which decomposed sugar as explained above. The latter investigators, however, had no idea at that time that the ferments were able to fix the nitrogen of the air, and the investigation is mentioned simply to call attention to the fact that these ferments are very widely diffused, since they were found in all the soils studied. These organisms are all anaerobic, and it would seem surprising that they should grow in a medium so thoroughly aerated as arable soil; but this has been explained by Winogradsky as follows: The organisms which fix nitrogen are capable of action only when associated with certain common species of organisms which are capable of oxidizing organic matter and which thus surround the anaerobic forms with an atmosphere charged with carbon dioxide and deprived of oxygen. Winogradsky further suggests that the hydrogen set free in the

<sup>1</sup> Ann. Agron., 9 (1883), p. 5; 10 (1884), p. 5.

decomposition of the carbohydrates furnishes ammonia, which is assimilated by the micro-organisms and used in the formation of tissue. It is not, therefore, simply the nitrogen which has recently been drawn from the air which is utilized by plants. They assimilate also the nitrogen derived from vegetable and animal remains.

The work of Pasteur has shown that the action of micro-organisms is necessary to the transformation of the complex organic substances of the tissues of living plants into the simple forms which may be assimilated by plants. Without these organisms life would be impossible, as Pasteur himself has said, because the work of death would be incomplete. By their intervention the complex substances are burned, the carbon passing into the form of carbon dioxide, the hydrogen into water, and the nitrogen into ammonia; and in these different forms the matter is again carried into circulation.

It often happens that vegetable matter remains for a long time in the form of humus; but even in this form it is utilized by plants. The humus is constantly subjected to the oxidizing action of the lower organisms and undergoes gradual decomposition. The ammonia produced by the decomposition of the humus is assimilated by plants as well as the readily available product of oxidation, nitric acid.

Schloesing and Müntz 20 years ago showed that nitrates are formed in the soil by the action of organisms. More recently Winogradsky has demonstrated that the action of two different organisms are necessary for the transformation of ammonia into nitrates—one converts ammonia into nitrites and the other completes the oxidation, producing nitrates. We thus see that micro-organisms seize upon the nitrogen of the air and convert it into organic compounds; they convert vegetable matter into humus, and then break down this humus, producing ammonia and finally nitrates. At every step they perform a useful work, and are valuable auxiliaries of agriculture.

There are, however, other organisms which interfere with the work of the beneficial kinds. Bréal observed several years ago that there is an aerobic organism which decomposes nitrates and sets elementary nitrogen free. This organism is abundant in vegetable debris, especially in straw. It is also encountered in the excrement of domestic animals. The extent to which the losses of nitrogen in arable soils is due to the action of this denitrifying organism and the conditions most favorable to its action are questions which require further investigation.

#### THE DIFFERENT FORMS IN WHICH NITROGEN IS UTILIZED BY PLANTS.

If we follow the example of Boussingault and plant a sunflower seed in a sterile soil to which the necessary mineral matter and increasing amounts of nitrates are added, or if we repeat the experiment of Hellriegel and plant barley in well-washed sand to which sufficient mineral matter and increasing amounts of calcium nitrate are added, we will find that the crop produced increases with the amount of

nitrate added. In Hellriegel's experiments less than 1 gm. of dry matter was produced when nitrates were not added, the production of dry matter increasing to 25 gm. when sufficient nitrates were supplied.

These experiments, however, simply demonstrated in an exact manner facts which were already well known in practice. The consumption of nitrate of soda would never have reached its present enormous proportions if farmers had not learned to appreciate the efficacy of nitrates as a fertilizer. At the present time they enter into all fertilizer formulas. The application of this fertilizer is necessary, because we are not yet able to so control nitrification in the soil that it can be made to furnish sufficient nitrates for the demands of the crop at exactly the time in the spring when they are most needed. Nitrates are produced only in warm and moist soils, and they are found in the drainage water in larger proportion in autumn than in any other season. Fortunately the roots of living plants have great capacity for retaining the nitrates and thus reduce the loss in drainage.

If wheat roots are drawn from the soil during the winter, dried, and soaked in sulphate of diphenylamin they will take on a deep blue coloration. The amount of nitrates contained in wheat roots is surprisingly large. The author has found as much as 1 per cent in dried roots, but the proportion decreases as growth advances. They pass from the roots to the stems and then to the leaves, where they are used in the formation of albuminoid substances. It might be a matter of surprise that substances which are so easily soluble in water as the nitrates can nevertheless be taken up and retained by roots even when surrounded by moist soil. Demoussy has shown that nitrates can not be removed from the roots by washing in cold water, but are extracted when the roots are treated with warm water or when they are subjected for some time to an atmosphere of chloroform and then washed with cold water. It appears, therefore, that the nitrates penetrate by osmosis into the interior of the cells and form unstable combinations with the protoplasm, resuming their normal state only when the protoplasm is modified by elevation of temperature or the action of chloroform.

Experience has shown that whether nitrates are formed in the soil by the action of micro-organisms or introduced in the form of fertilizers they exert a decided influence upon the crop. Nitrates are not formed in soils like those of meadows or forests, which are highly charged with decaying organic matter, since these soils are acid and therefore do not furnish a suitable medium for the nitric ferment. Liming renders such soils more favorable to the activity of the nitric organisms.

In meadow and forest soils nitrogen appears to be taken up by plants in the form of ammonia. Müntz,<sup>1</sup> Bréal,<sup>2</sup> and Pagnoul<sup>3</sup> have reported

<sup>1</sup>Ann. Sci. Agron., 1896, I, No. 2, p. 161.

<sup>2</sup>Ann. Agron., 22 (1896), p. 485 (E. S. R., 8, p. 386).

<sup>3</sup>Ann. Agron., 19 (1893), p. 274.

experiments which indicate that nitrogen is easily absorbed by plants in this form. Bréal<sup>1</sup> has shown that nitrogen is also taken up by plants in the form of humates of lime or potash.

Hellriegel has shown in experiments with barley fertilized with variable amounts of nitrates that the amount of water transpired by the plant per gram of dry matter increases as the amount of nitrate applied decreases. Barley, which received the most favorable amount of nitrates, evaporated 263 gm. of water per gram of dry matter produced. The plants which received no nitrates and which made a sickly growth evaporated from 700 to 800 gm. of water per gram of dry matter. Normal, vigorous plants obviously evaporate more water than sickly ones, but if we calculate the ratio of the quantity of water transpired to the weight of dry matter produced we find that the proportion is greater in the sickly than in the vigorous plants. This fact may be useful in determining the efficacy of a fertilizer.

By pursuing this method of investigation the author found that the Gramineæ and Leguminosæ do not take up and utilize plant food in the same manner. The Gramineæ are especially benefited by chemical fertilizers, particularly nitrates, while they do not utilize humus substances to very great advantage. On the other hand, Leguminosæ are more benefited by the humates than by nitrates or ammonia salts.

Rye grass and clover were planted in large pots, each of which contained 50 kg. of soil exhausted by continuous cropping. Equal amounts of phosphoric acid, potash, and nitrogen were applied. In one case the nitrogen was applied in the form of nitrates, in the other in the form of humate. A black extract from manure which contained a mixture of humate of potash and humate of ammonia was also used. At the end of the experiment it was found that the rye grass which had received no manure had transpired 682 gm. of water per gram of dry matter, that which had received humates 435 and 469 gm., and that which had received only chemical fertilizer 233 gm. The results were quite different with clover. In this case the transpiration was: Without manure 454 gm., with chemical fertilizers 398 gm., and with humates 272 and 265 gm. These results confirm the conclusions of Bréal, Snyder, and Lawes and Gilbert. The latter have shown at Rothamsted that it was impossible to grow clover continuously on the same land unless the soil was abundantly supplied with organic manures.

To summarize, then, nitrogen is taken up by plants in the form of nitrates, ammonium salts, and alkaline humates. The Leguminosæ can utilize free nitrogen only when it has been brought into combination by the action of the organisms of the root tubercles. It has frequently been claimed that other plants besides the Leguminosæ are capable of absorbing free nitrogen, but it has been shown that this absorption does not take place without the intervention of the organisms which fix nitrogen.

---

<sup>1</sup> Ann. Agron., 20 (1891), p. 353 (E. S. R., 6, p. 284).

## FORMATION OF NITROGENOUS MATTER.

This is a subject of which little is known. A study of the changes which take place in the atmosphere surrounding a plant shows that the ratio of carbon dioxid absorbed to oxygen evolved is much less than unity. Since in a study of assimilation in a detached leaf Boussingault found this ratio to be equal to unity it is natural to attribute the larger part of the excess of oxygen thus found to reduction of nitrates; for if the chlorophyll cell is capable under the influence of sunlight of reducing so stable a compound as carbon dioxid it is fair to assume that it could more easily reduce nitric acid. It is probable that the nitric acid is transformed into ammonia which unites with carbohydrates to form amids, which by successive steps are transformed into the complex albuminoids. This, however, is simply an hypothesis which is not based upon exact observation.

## CONCLUSIONS.

When Priestley in 1771 made the discovery that plants purify an atmosphere which has been vitiated by the respiration of animals he proclaimed the solidarity of two kingdoms, an idea which gradually took definite shape.

Plants, agents both of reduction and of synthesis, decompose the carbon dioxid of the air under the influence of sunlight and elaborate organic matter, while the animal burns this organic matter and exhales the carbon dioxid which nourishes the plant. The plant stores up in its reserve materials the energy drawn from the sun and the animal consumes these materials, converting the energy into heat and work.

Our views regarding this subject were broadened by the investigations of Pasteur, who demonstrated that the innumerable plants without chlorophyll as well as the micro-organisms which swarm in the soil are, like animals, destroyers of organic matter and producers of carbon dioxid. Indeed, it seemed at first that their rôle was simply to "complete the work of death," reducing the organic matter to those simple forms which can be utilized by plants. One of their most important functions, however, was ignored until Berthelot showed that these organisms are not only agents of reduction, but that some of them are agents of synthesis which draw into the cycle of life the most refractive of elements—nitrogen—while others have the power of fixing the free nitrogen of the air. The solidarity of living beings thus appears under another form. The fixers of nitrogen live and work only to destroy the organic matter elaborated by the fixers of carbon—the chlorophyll plants.

If the tree holds sway on the plains, proudly spreading its branches; if the valleys are covered with bright colored herbage; if the reaper gathers the golden sheaves, it is due to the humble workers hidden in the depths of the soil, one class fixing the nitrogen in complex combinations, and others taking up this matter, simplifying it, and convert-

ing it into ammonia and nitrous and nitric acids. Others, again, of which we are just beginning to learn, destroy this work and set the nitrogen free. A part of the work accomplished, however, is not undone, for the nitrates which are taken up by the roots rise to the leaves and help form the complex substances necessary to animal life.

Although the plant profits by the work of the micro-organisms, it assists them in its turn. The roots of the plant and its discarded leaves falling like a beneficent rain furnish the carbonaceous matter necessary to the life and work of the fixers of nitrogen.

The harmony of nature increases in beauty as we slowly arrive at a better understanding of it, and our admiration increases with the new knowledge of the solidarity of the fixers of nitrogen and the fixers of carbon, which mutually assist each other and insure the continuance of life upon the surface of the earth.

## RECENT WORK IN AGRICULTURAL SCIENCE.

### CHEMISTRY.

**A contribution to the method of extracting fat,** E. VOIT (*Ztschr. Biol.*, 35 (1897), No. 4, pp. 555-582).—It has been claimed that the method of determining fat in meat by extraction with ether does not give accurate results. The author reports in detail the ether-extraction method ordinarily followed at Munich which he believes to be reasonably accurate. This differs in some points from that in use elsewhere. It is as follows: Duplicate samples of meat are dried on a water bath at a temperature under 80° C. The substance thus dried often absorbs water when pulverized, therefore it is treated with sufficient alcohol to render it crummy and then dried until the odor of alcohol is no longer noticeable. After standing for some time covered but accessible to the air it is pulverized. Samples of the material thus prepared are used for further analysis.

A number of experiments were made by Krummacher to test the accuracy of this method as compared with the digestion method of estimating fats as proposed by Dormeyer (*E. S. R.*, 7, p. 919). The conclusion was reached that when the extraction with ether was properly carried out with small quantities of substance as free from water as possible 24 hours extraction was sufficient. In the majority of cases extraction with ether alone removed all the fat. It is certain that 95 per cent of the fat may be so obtained, and this method may be used unless greater accuracy is desired. There are still sources of error in the method of extraction by ether which are not understood.

**On the determination of fat and casein in feces,** H. POOLE (*Jour. Amer. Chem. Soc.*, 19 (1897), No. 11, pp. 877-881).—In connection with the study of the feces of a child fed an exclusive milk diet the author proposes tentatively the following method of determining the fat and casein. The ether extract of the dried feces, which contains both fat and cholesterol, is evaporated until nearly dry at 100° and then heated to 110° until dry. It is then saponified with alcoholic potash, water added, and the mixture boiled to expel the alcohol. The filtered solution, which should be clear and opalescent, is extracted with ether several times to remove the cholesterol. The aqueous solution is evaporated until nearly dry and then taken up with water, the fatty acid being determined by any of the usual methods.

To determine the casein the feces are extracted with ether, water, and alcohol, then dried and digested with hydrochloric acid (70 per cent water) for several hours at about 50°. The casein is dissolved, leaving the epithelial cells and other matter undissolved. After evaporating the hydrochloric acid solution the nitrogen is determined by the Kjeldahl method and the casein calculated.

**Chemical and bacteriological investigations on the fermentation of fresh grass**, O. EMMERLING (*Ber. Deut. Chem. Gesell.*, 30 (1897), p. 1869; *abs. in Chem. Ztg.*, 21 (1897), No. 89, *Repert.*, p. 256).—Fresh grass was packed in a large covered earthenware jar. After 24 hours the temperature of the grass increased to 26° C., as shown by a thermometer in the cover of the jar. It remained for some time fairly constant at this temperature and then decreased slowly to room temperature. For four weeks there was a slow but constant evolution of gas made up of 63 per cent carbon dioxid and 36 per cent nitrogen. No methan was detected. When removed from the jar the grass had a brownish color, acid reaction, and an odor resembling an ester. As shown by analysis, the amount of nitrogen free extract and protein was diminished, the other constituents being relatively increased. Chinon was identified in the ether extract. The bacteria found and the chemical decomposition of the constituents of the grass due to their action are discussed.

**The preparation of a carbohydrate from egg albumin**, J. G. SPENZER (*Ztschr. Physiol. Chem.*, 24 (1898), No. 4, pp. 354-357).

**Microscopic examination of water**, C. MEZ (*Mikroskopische Wasseranalyse. Berlin: J. Springer, 1897*).—A manual giving especial attention to the analysis of potable water and sewage. The micro-organisms in fresh water are discussed.

**Contribution to the microscopical examination of foods and feeding stuffs**, A. HEBBRAND (*Forsch. Ber. Lebensmtl.*, 4 (1897), No. 11, pp. 306, 307).

**Detection of formalin in food** (*Ztschr. Nahr. Untersuch. u. Hyg.*, 12 (1898), No. 2, pp. 29, 30).

**Apparatus for rapid and accurate determination of milk fat**, ELLENBERGER (*Ztschr. Nahr. Untersuch. u. Hyg.*, 11 (1897), No. 22, pp. 373, 374, fig. 1).

**Experiments on the amount of lead in tin plate and canned goods**, P. CARLES (*Jour. Hyg.*, 23 (1898), No. 1116, pp. 64-66).—A method of estimating lead electrolytically as PbO<sub>2</sub> is recommended.

**Introduction to the chemical analysis of wines**, E. BORGMANN (*Anleitung zur chemischen Analyse des Weines. Wiesbaden: C. W. Kiedel, 1897, 2. ed. by Th. W. Fresenius*).

**Experience in the analysis of sweet wines**, E. VON RAUMER (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 1898, No. 1, p. 49; *abs. in Chem. Ztg.*, 22 (1898), No. 9, *Repert.*, p. 19).

**Determination of acid in beer and other liquids containing acid phosphates**, A. OTT (*Ztschr. Gesam. Brauw.*, 20 (1897), p. 540; *abs. in Chem. Ztg.*, 22 (1898), No. 9, *Repert.*, p. 19).

**Reflux condensers**, B. H. HITE (*West Virginia Sta. Rpt. 1896*, pp. 64, 65, fig. 1).—A condenser designed for use over beakers is described. "[It] consists of a round flask with a short neck, closed by a two-hole rubber stopper, through which passes the inlet and outlet tubes. The inlet tube extends nearly to the bottom of the flask, the outlet tube about halfway to the bottom, and upon the depth to which the outlet tube is inserted into the flask may be made to depend the depth of the water

in the flask, as the space above the lower end of this tube is filled with air. . . . The condenser rests on the mouth of the beaker and requires no other support."

**Apparatus for extracting with ether**, B. H. HITE (*West Virginia Sta. Rpt. 1896, pp. 60-64, pl. 1*).—An apparatus is described which follows automatically the method of washing on the filter, allowing one quantity of solvent to run through before another is added, thus combining the advantages of the siphon and percolator classes of extractors. All joints with which the ether comes in contact are closed with mercury. The rate of siphoning is easily controlled in the apparatus described and the solvent is recovered "without the use of any accessory apparatus and without the loss which is always incurred by opening an extractor to attach the accessories. The recovered ether is retained immediately under the condenser, where there is little danger of loss."

**Drying apparatus**, B. H. HITE (*West Virginia Sta. Rpt. 1896, pp. 57-60, pl. 1*).—A convenient apparatus for drying in hydrogen is described in detail.

**Chemical division**, H. J. WHEELER (*Rhode Island Sta. Rpt. 1896, pp. 211-220*).—A brief summary of the work of the year in this department of the station, including analyses of wood ashes, slag, floats, aluminum phosphates, superphosphates, raw and dissolved bone, tankage, Peruvian guano, dried blood, sulphate of ammonia, nitrate of soda; nitrate, carbonate, muriate, and sulphate of potash; soda ash, common salt, Epsom salts, refuse from soap works, wool waste, mangel-wurzels, sugar beets (limed and unlimed), Fungiroid, and water.

## BOTANY.

**The relation of nutrient salts to turgor**, A. B. COPELAND (*Bot. Gaz., 21 (1897), No. 6, pp. 399-416*).—It is claimed that turgor can not supply the energy necessary for growth, since growth occurs without turgor stretching, and abnormally slow growth is more likely to increase and rapid growth to decrease turgor than be influenced by it. However, turgor probably plays an important function in plant economy.

The author has investigated by means of water cultures *Phaseolus multiflorus*, *P. vulgaris*, *Pisum sativum*, *Sinapis alba*, *Eragopyrum* sp., and *Zea mays* noting the effect of various salts on the turgor of the plant. While various compounds were used, the effect of potassium and sodium were principally noted. It was found that potassium presented in solution to the roots of plants causes the cells of both root and stem to exhibit a higher turgor than they do when it is replaced by sodium. This seems to indicate that potassium is a direct factor in the turgor of the plant, and there seems to be no experimental ground for attaching this significance to any other constituent of the mineral food of plants. When offered to the roots, potassium is taken up and stored in the cell sap where it becomes an important part of the osmotically active material which keeps the cell and plant turgid. This function is not shared by sodium, which is considered useless to the plant.

**Homology of organs as shown in cuttings**, L. C. CORBETT (*West Virginia Sta. Rpt. 1896, pp. 194-196, pls. 2*).—The author reports upon cuttings grown from potato plants in which about 5 in. of the top-most portion of the growing branches were removed. These cuttings took root readily and small tubers appeared either at the cut surface where the roots develop or from the axil of the leaf, the latter being the

more common place. As soon as these tubers were fully matured the roots and top of the original cuttings began to dry up. When cuttings were used in which no joints or nodes were placed under the soil the tubers developed from the axils of the leaf in every case. It was demonstrated that the aerial tubers would germinate and produce tops, but the resulting tubers were never larger than those planted.

Similar experiments were conducted with *Stachys floridana*, in which tubers were developed in the axils of the leaf even before the cuttings had made root, but they were never produced above ground.

**Increase of the nitrogen of the soil by white mustard**, S. VON KOWERSKI (*Inaug. Diss., Halle, 1895; abs. in Jour. Chem. Soc. [London], 72 (1897), No. 121, II, p. 590*).—A number of pot experiments were made in which white mustard was grown in 2 lots of arable soil containing 0.1149 and 0.1261 per cent of nitrogen, respectively. There were also 2 pots in which peas and mustard were grown together. The pots were sterilized, but no attempt was made to maintain their sterility, the whole experiment being conducted out of doors. Each of the pots received an equal quantity of sodium nitrate as well as mineral manure and each showed a gain of nitrogen. The gain was from 2 to 7 times greater in the unsterilized than in the sterile soil, and there was also a greater gain of nitrogen under the influence of nitrogenous manure than when the soil was unmanured. The author concludes that the fixation of free nitrogen took place through the influence of the microorganisms present in the soil, the white mustard itself not being able to assimilate elementary nitrogen. Peas grown in rich soil do not assimilate free nitrogen even when their roots bear well developed tubercles.

**The permeability of tree trunks to gases**, H. DEVAUX (*Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 23, pp. 979-982*).—By means of a specially devised apparatus the author has been able to observe a very considerable gaseous exchange between tree trunks and the air.

He found that on the larger trunks lenticels are abundant and they are frequently larger and more open than on the smaller branches. In some trees such as *Picea excelsa* and *Populus alba* the lenticels are well-developed yet they are almost completely closed for the most of the time.

The author states that the crustaceous lichens which often cover tree trunks do not sensibly affect the gaseous exchange through the lenticels.

**Root tubercles in water cultures**, H. A. WEBER (*Jour. Amer. Chem. Soc., 20 (1898), No. 1, pp. 9-12, fig. 1*).—A form of apparatus that has proved very efficient in studying the development of root tubercles is described and figured. Plants can be grown in any kind of culture medium. The apparatus secures a constant level and thorough aeration of the culture medium and peas have been readily grown to fruiting in it.

An experiment with peas is briefly described. In it one lot of plants was grown in a complete solution, a second in the same solution but

without any nitrogen, and the third lot the same as the second with the addition of an infusion of soil where peas had been grown. No. 1 grew well, No. 2 died of nitrogen starvation, and No. 3 grew well for about 10 days, when the plants began to show appearances of nitrogen starvation and no tubercles were visible. A few days later the plants began to recuperate and the growth became normal and vigorous. On the fifteenth day tubercles were abundant.

[The author is in error in saying that the subject of nitrogen assimilation has only been studied in connection with sterilized soil or sand, as water cultures have been employed by Hellriegel, Hiltner, Frank, Lotsy, and others.—ED.]

**The tensile strength of cell walls**, H. H. DIXON (*Ann. Bot.*, 11 (1897), No. 10, pp. 585-588).—The author has conducted a series of experiments to ascertain the coefficient of safety against osmotic pressure in plant cells. From data collected from the breaking stress of fibers of cotton and other plants and comparing the area of these fibers with those of the cell walls of many plants he finds that every cell of the leaf is able to sustain the high osmotic pressures which give rigidity to the leaf and, so far as the strength of the cell walls is concerned, much higher pressures might exist.

**On the composition of the membranes of some fungi**, C. TANRET (*Bul. Soc. Chim. Paris*, 3. ser., 17 (1897) No. 20-21, pp. 921-927).—After treating the mycelium of *Aspergillus niger* with water, alcohol, ether, cold caustic soda, and sulphuric acid, the author states that chitin is present associated with a carbohydrate called fungose, which is similar to, if not identical with that found in yeast, ergot, agarics, and boletus. Having been found in such dissimilar fungi the author believes that fungose is a constituent of the membranes of all fungi.

**The plants of saline soils**, A. FERET (*Monde des Plantes*, 2. ser., 7 (1897), No. 96, pp. 193-195).

**Plants and their environments**, J. COSTANTIN (*Le végétaux et les mélieux cosmiques*. Paris: F. Alcan, 1898, pp. 296, figs. 296).

**A revision of the diagnosis of the species of Hymenomycetes**, M. BRITZELMAYR (*Bot. Centbl.*, 73 (1898), Nos. 5, pp. 129-135; 6, pp. 169-175).

**Critical studies of the North European forms of *Agrostis***, A. S. MURBECK (*Bot. Notiser*, 1898, No. 1, pp. 1-14).

**The effect of drought upon certain plants**, CLARA CUNNINGHAM (*Proc. Indiana Acad. Sci.*, 1896, pp. 208-213, pls. 2).—An experimental study was made on the effect of drought on the different tissues of plants, the subject of the experiments being oxalis, canna, corn, beans, castor beans, and cucumbers.

**Development of roots from cuttings**, L. C. CORBETT (*West Virginia Sta. Rpt.* 1896, pp. 196-199, pls. 3).—The author discusses the development of roots from cuttings, and states that they do not have their origin in the callus, but grow from the fundament formed in the tissue of a portion of the plant used as a cutting in a similar manner to that of the development of new roots from the root or the plant axis of a seedling.

**A device for measuring plant growth**, L. C. CORBETT (*West Virginia Sta. Rpt.* 1896, pp. 236-240, pl. 1).—The author figures and describes a form of auxanometer for which the advantage of a record made in ink in the form of a platted curve is claimed.

The action of ammonium salts on *Aspergillus niger*, C. TANRET (*Bul. Soc. Chim. Paris*, 3. ser., 17 (1897), No. 20-21, pp. 914-921).—The author experimented with the nitrate, sulphate, chlorid, and phosphate of ammonia, and found the fungus was able to absorb certain quantities of these salts, part of which was utilized, and the rest thrown off.

The pigmy panic grass (*Panicum pygmæum*), J. H. MAIDEN (*Agr. Gaz. New South Wales*, 9 (1898), No. 1, p. 32, pl. 1).—Descriptive notes of this grass, which is said to be valuable in rather dense shade.

### FERMENTATION—BACTERIOLOGY.

Concerning a ferment of cellulose, V. OMELIANSKI (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 23, pp. 970-973).—The author announced in 1895<sup>1</sup> the isolation of a bacillus capable of fermenting pure cellulose, such as cotton and flax fibers. In the present paper the principal physiological and morphological characteristics of the organism are described.

In order to bring about the fermentation small strips of Swedish filter paper are placed in bottles filled with a suitable culture solution to which a small quantity of slime or soil rich in vegetable material is added. In place of the mineral matter of the culture medium river water may be substituted. Ordinarily fermentation will be shown by the liberation of gas in from 6 to 10 days at 35° C. Examinations of the filter paper in 3 weeks or a month will show an advanced state of decomposition and the presence of colonies of the organism from which pure cultures can be easily made. The organism when young is 4 to 8 $\mu$  by 0.3 to 0.5 $\mu$  in diameter. When old, it sometimes attains a length of 12 to 15 $\mu$ . It is slightly oval or rounded and spore forming. The spores attain a diameter of 1.5 $\mu$ , resist a temperature of 90° C. for 25 minutes, but are instantly killed at the boiling point. The bacillus in any of its stages of growth is not stained by iodine. It does not grow on gelatin culture media. On gelose it forms small colonies, and while making slight growth on cooked potatoes, it degenerates rapidly.

In the author's experiments filter paper, cotton, and an amorphous precipitated cellulose were placed in a solution containing sulphate of ammonia to which were added 1 per cent peptone and 0.5 per cent asparagin, and the organism introduced. The results of some of the experiments show that from 79 to 96 per cent of the cellulose was destroyed in from 3½ to 5 months. In an extreme case 5 gm. of paper was completely fermented in 3 months. An examination of the residue after washing it with a very weak solution of hydrochloric acid

<sup>1</sup> *Compt. Rend. Acad. Sci. Paris*, 121 (1895), p. 653.

showed it to be almost wholly made up of spores of the organism, and no color reaction with chlorzinc-iodin was apparent.

The gas fermentation resulted in the liberation of hydrogen and carbon dioxid with no indication of marsh gas.

Volatile acids were produced in considerable quantity, valerianic acid being the most common, but there were no traces of fixed acids.

Some of the higher alcohols were present, but in quantities too small for determination.

**Have the common yeasts pathogenic properties?** KATHERINE E. GOLDEN (*Proc. Indiana Acad. Sci.*, 1896, pp. 184-188).—The author made a study of common yeasts such as are taken into the system through various sources to ascertain whether any of them possess pathogenic properties.

The first series of experiments indicated that yeasts taken into the stomach of rabbits caused neither discomfort nor lesions in any of the organs, even when a fermentable substance was eaten at the same time. The experiments also indicated that certain yeasts readily pass through the intestinal tract without being killed, although their vigor is somewhat impaired.

A second set of experiments, in which the yeasts were introduced into the circulation, indicated that the common yeasts used possessed no toxic properties for rabbits and guinea pigs. None of them multiplied when introduced into the animal body, and in 4 cases they were destroyed within 48 hours.

**A new pigment-forming saprophyte,** W. W. RODSEWITSCH (*Vruch [St. Petersburg]* (1897), No. 15, p. 436; *abst. in Centbl. Bakt. u. Par.*, 2. Abt., 3 (1897), No. 21-22, p. 591).—While examining heads of wheat for *Tilletia levis* the author found quite a number of bacteria, among them *Bacterium megatherium*, *Micrococcus tetragenus*, *M. roseus*, and an undescribed bacillus. The organism is about  $0.5 \mu$  long, grows best between  $20^{\circ}$  and  $37^{\circ}$  C., and was killed by an exposure of 1 hour to a temperature of  $70^{\circ}$  C. Subcutaneous injections on guinea pigs showed no pathogenic properties. The bacillus forms an abundant yellow pigment, especially when grown on potatoes or on grape sugar agar for 1 to 2 months, the substratum becoming wholly covered with the yellow pigment. Spore formation was not apparent.

**The supposed alcoholic enzym in yeast,** J. R. GREEN (*Ann. Bot.*, 11 (1897), No. 44, pp. 555-562).—Following the directions of Buchner<sup>1</sup> the author sought to isolate under pressure the enzym reported to exist in yeasts. In the author's experiments the evolution of carbon dioxid and formation of alcohol did not correspond to the change in the specific gravity of the solutions. In one series there was no increase in the quantity of alcohol at the end of the experiment. Considering the evidence of his experiments the author believes that in the yeasts used there was no enzym such as described by Buchner.

**Enzymic ferments in plant physiology,** F. A. WAUGH (*Science, n. ser.*, 6 (1897), No. 156, pp. 950-952).

<sup>1</sup> Ber. Deut. Chem. Gesell., 30 (1897), p. 117.

**Systematic bacteriology**, EICHLÖFF (*Milch Ztg.*, 26 (1897), Nos. 51, pp. 809, 810; 52, pp. 828-830; 27 (1898), No. 1, pp. 7, 8).

**A study of the pathogenic bacteria of Cete oysters**, A. SABATIER, A. DUCAMP, and J. M. PETIT (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 19, pp. 685-689).

**Diastatic fungi and their utilization**, J. TAKAMINE (*Amer. Jour. Pharm.*, 70 (1898), No. 3, pp. 137-141, figs. 2).

**A simple and accurate method of testing diastatic substances**, J. TAKAMINE (*Amer. Jour. Pharm.*, 70 (1898), No. 3, pp. 141-143).

**Some of the properties of the oxydase of wines**, A. BOUFFARD (*Ann. École Nat. Agr. Montpellier*, 9 (1895-'96), pp. 213-217).

**Recent researches on the oxydases**, G. BERTRAND (*Ann. Agron.*, 23 (1897), No. 9, pp. 385-399).

**The effect of heating on diastatic ferments**, A. PUGLIESE (*Arch. Physiol. [Pflüger]*, 69, p. 115; *abs. in Chem. Ztg.*, 22 (1898), No. 9, *Repert.*, p. 21).

**The biology of Bacillus baccarinii**, L. MACCHIATI (*Bul. Soc. Bot. Ital.*, 1897, pp. 156-163; *abs. in Ztschr. Pflanzenkrank.*, 7 (1897), No. 6, pp. 354, 355).—The life history of *Bacillus baccarinii*, the cause of the "mal nero" of grapes is given.

**Contribution to the question of the differentiation of Bacillus aerogenes and Bacillus coli communis**, J. C. T. SHEFFER (*Arch. Hyg.*, 30 (1897), No. 4, pp. 291-303, figs. 3).—As shown by cultural means and agglutination phenomena these bacilli are distinct.

**The effect of the so-called monochromic light on bacterial development**, BECK and SHULTZ (*Ztschr. Hyg. u. Infektionskrank.*, 23 (1897), p. 490; *abs. in Centbl. Bakt. u. Par.*, 2. Abt., 3 (1897), No. 21-22, p. 603).—Experiments were made with Landolt's color screen to determine the effect of its light on bacteria. Comparisons were made with diffused light and direct light. The monochromic light was found to be without effect on the growth of the bacteria. Röntgen rays were also investigated and found to be without effect on bacteria.

**Agar as a medium for the bacteriological examination of water**, F. HESS (*Centbl. Bakt. u. Par.*, 1. Abt., 21 (1897), No. 24-25, pp. 932-937).—Agar in certain respects it is claimed is superior to gelatin for the bacteriological examination of water and is recommended because it does not liquefy. The medium must contain 1 per cent of agar and the water in the bath in which the agar tubes are placed must be heated to 38 or 40° C. before much water is added to it. Such an amount of water is used as will produce about 200 colonies per plate. To avoid mistakes at least 2 control plates should be made. The plates are to be turned face downward, since in this position they are less likely to dry.

## ZOOLOGY.

**A revision of the North American bats of the family Vespertilionidæ**, G. S. MILLER (*U. S. Dept. Agr., Division of Biological Survey, North American Fauna No. 13, pp. 135, pls. 3, figs. 40*).—This is a purely technical monograph on the North American Vespertilionidæ. After some general questions, such as changes in color of specimens preserved in alcohol, sexual variation, age variation, geographical variation, geographical distribution, migration, measurements, and illustrations are discussed, a lengthy review of the nomenclature of the subject is given, followed by a list of North American bats, comprising 46 species and subspecies recognized as occurring north of Panama and in the West Indies. A detailed systematic description of the various species is given. These fall under the following genera, the numbers

denoting the number of species: Antrozous, 2; Euderma, 1; Corynorhinus, 3; Myotis, 15; Lasionycteris, 1; Pipistrellus, 5; Vespertilio 6; Lasiurus, 6; Dasypterus, 1; Nycticerius, 2; and Rhogeessa, 4.

A comparative table of names used for North American bats is given.

**Antagonism between the venom of the Vespidae and that of the viper—the first a vaccine against the second, C. PHISALIX** (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 23, pp. 977-979).—Glycerin extracts of the poison of the bee and the wasp were made by soaking the entire insects in the glycerin and also by treating similarly the poison gland. By the first process other substances were evidently extracted, but it is stated that a comparison of the effects of the extracts obtained in the 2 ways shows that these substances do not affect the results. A poison obtained from the sacs of 5 insects was inoculated into a guinea pig and found to lower the animal's temperature some 4° in 36 hours, and to produce an œdema about the inoculated spot that finally extends over the animal and causes a mortification of the skin. But when 1 to 3 cc. of the glycerin extract was used no appreciable trouble is caused. The œdema disappears quickly. The animal organism, however, undergoes such a change that the future injection of viper venom does not have its usual effect, even if the dose is sufficiently large to kill an uninoculated animal in from 4 to 5 hours.

The duration and intensity of the immunity are found to vary according to the dose of the extract. A guinea pig that had received the poison from the vesicles of 15 insects was perfectly resistant to viper venom at the end of a month. One that had received 2 cc. of the extract was found to be immune for 11 days. In one that had received 1 cc. the immunity became enfeebled toward the fifth day. A smaller dose,  $\frac{1}{2}$  cc. was found to be insufficient to produce immunity.

Endeavoring to determine the nature of the immunizing substance, the author heated the venom of the insects to 80°, 100°, and 120° for 20 minutes and found that the immunizing power was not destroyed. The venom was filtered on porcelain and inoculated against a dose of  $3\frac{1}{2}$  cc. of viper venom and found not to prevent, though it considerably retarded death. An alcohol extract of the venom was found to produce an œdema and at the same time act as a vaccine against the viper venom. Agitated with chloroform it gives up a large part of its substance. Studies of the chloroform extract showed that the immunizing substance of the insect venom is neither an alkaloid nor an albuminoid. Its nature still remains to be determined.

**Passing of the bluebird, C. C. ABBOTT** (*Pennsylvania Dept. Agr. Rpt. 1896*, pp. 374-376).—This is a reprint of a newspaper article in which it is shown that the decrease in the number of bluebirds is largely due to the English sparrow.

**The common food fishes of Pennsylvania, W. E. MERRIAM** (*Pennsylvania Dept. Agr. Rpt. 1896*, pp. 569-598, pls. 2).—The habits, etc., of the shad, herring, whitefish, sunfish, common sunfish (pumpkin-seed, sunny or tobacco box), long-eared sun-

fish, blue sunfish, strawberry bass, rock bass, black bass, yellow perch, striped bass, pike, catfish, eel, and chub are briefly discussed, and some pieces of fishing apparatus described.

**Fish culture in Ontario**, G. A. MACCALLUM (*Ontario Dept. Agr. Rpt. 1896, pp. 201-208, figs. 10*).—The fact that farmers may render their land more productive and their families more comfortable by adding fish farming to their customary pursuits is noted. The requirements for carp ponds are briefly stated. Carp should not be raised with other fish, and frogs, turtles, snakes, etc., should be kept out of the pond. The black water beetle (*Hydrophilus piccus*), the yellow banded water beetle (*Dytiscus marginalis*), the dragon fly (*Aeschna*), the water flea (*Gammarus pulex*), and the bladder wort (*Utricularia vulgaris*) are noted as fish enemies.

**A revision of the American moles**, F. W. TRUE (*Proc. U. S. Nat. Mus., 19 (1897), pp. 1-113, pls. 4, figs. 46, maps 4*).

**Transplantation experiments with Lumbricidæ**, E. JOEST (*Arch. Entwick-lungsmech., 5 (1897), pp. 419-569, pls. 2; abs. in Zool. Centbl., 4 (1897), No. 24, pp. 832-836*).—In these studies, in which the morphology and the physiology of the transplantations are discussed. *Lumbricus rubellus* and *Allolobophora terrestris* were employed, mostly young worms without clitellum being used. It was found that 2 bodies of the same individual or of the same species would unite in a relatively short time, but the parts of different species would not unite so readily. The nervous system seems to have a very decided influence over the regeneration of the parts. An interesting fact is noted, that the worms can live for a year without food.

**Treatise on concrete zoology. Vol. I, The cell and the protozoa**, Y. DELAGE and E. HEROUARD (*Traité de zoologie concrete. Tome I, La Cellule et les protozoaires. Paris: Schleicher Freres, 1896, pp. 584, figs. 870*).—The first of a series of 11 volumes, giving a summary of the animal kingdom. In this volume are discussed the cell and its functions, its structure, chemical composition, physiology, etc. The protozoa are described according to class, order, family, genus, and species.

## METEOROLOGY.

**Annual summary of meteorological observations in the United States, 1897** (*U. S. Dept. Agr., Weather Bureau, Monthly Weather Review, 25 (1897), No. 13, pp. 569-579, charts 5*).—This number of the Weather Review is devoted to an annual summary of observations on atmospheric pressure, temperature, precipitation, wind movement, cloudiness, and other meteorological phenomena "based essentially upon data received from about 150 regular Weather Bureau stations and 30 regular Canadian stations, all reporting daily by telegraph." The data are given in tables and charts and summarized in the text.

"The lowest annual averages [of temperature] within the United States were: Williston, 38.8°; Moorhead, 39.2°; Bismarck and Duluth, 39.5° each. The highest averages were: Key West, 77.2°; Jupiter, 74.1°; Tampa, 72.2°; Corpus Christi, 70.7°; Galveston, 70.2°.

"The mean annual temperature was above the normal at 101 stations, below at 20, and normal at 12. . . . Maximum temperatures equaling or exceeding 105° occurred at Shreveport, Topeka, Abilene, Phoenix, Yuma, Walla Walla, Redbluff, Sacramento, and Fresno. Minimum temperatures of—25° or lower occurred at Duluth, Moorhead, Bismarck, Williston, Minneapolis, St. Paul, Huron, and Havre.

"The only portions of the country not visited by frost, assuming that frost does not occur with air temperature above 32°, were the southern end of the peninsula of Florida and the coast line of southern California.

"The largest annual ranges of temperature were, as usual, in North Dakota and

the northern slope, viz, Havre, 140°; Bismarck, 138°; Williston, 136°, and Moorhead, 129°. The smallest annual ranges were: Key West, 40°; Eureka, 52°, and San Diego, 53°. . . .

"In 1894 precipitation was below average in every district east of the Rocky Mountains. In 1895 there was an excess of precipitation in the southern and middle slopes, but elsewhere between the Rocky Mountains and the Atlantic seaboard there was a marked deficiency. In 1896 there was an excess of rainfall in the extreme Northwest, the upper Mississippi Valley, the Missouri Valley, and the northern and southern slopes. The year 1897 opened with heavy rains in the lower Mississippi Valley, Tennessee, Alabama, and adjoining regions, and it seemed as if the period of diminished rainfall had come to a close. The rainfall of May was about average, except in the Gulf States, Arkansas, Missouri, and upper Mississippi valleys. The June rainfall was generally below the average, but in July unusually heavy rains fell throughout New England, the upper Lake Region, upper Mississippi Valley, Florida, and portions of the Ohio Valley, and the Middle and South Atlantic States. By the middle of August a drought had set in over practically all of the territory east of the Rocky Mountains, which was not broken in some localities until about the 1st of November, and the year ended as one of generally deficient rainfall.

"The stations having the largest deficiencies during 1897 are: Galveston, Texas, 19.44 in.; New Orleans, Louisiana, 17.05 in.; Raleigh, North Carolina, 16.94 in.; Wilmington, North Carolina, 16.66 in. The stations having the largest excesses are: Jupiter, Florida, 29.09 in.; Fort Canby, Washington, 12.88 in.; New Haven, Connecticut, 9.98 in. . . .

"[From] the accumulated departures of the total monthly precipitation from the normal . . . it appears that the total annual precipitation was normal in 1 district, above normal in 6, and below in the remaining 14. As in previous years, the greatest deficiency exists in the west Gulf States and lower Mississippi Valley. Precipitation has been below normal in this region since 1896. The deficit during 1897 has been steadily increasing in the Middle and South Atlantic regions, east and west Gulf, upper and lower Lake, Missouri, and upper Mississippi valleys, but a notable excess has accumulated in the Florida Peninsula. . . .

"The greatest frequencies [of thunderstorms] per station per annum were: South Carolina, 24.9; Florida, 24.3; Missouri and Tennessee, 22.6; North Carolina, 21. The smallest frequencies were: California, 2.6; Washington, 3.9; Oregon, 4.2."

**Report of the meteorologist, N. HELME** (*Rhode Island Sta. Rpt. 1896, pp. 363-369*).—This includes general remarks on the character of the weather during the year and a tabulated summary of observations on temperature, pressure, precipitation, cloudiness, and prevailing winds during each month of 1896 with a summary for the years 1890 to 1896, inclusive. The summary for 1896 is as follows:

*Temperature* (degrees F.).—Maximum, 93, May 10; minimum, —11, February 17; mean, 47.7; annual range, 104; highest monthly mean, 70, July; lowest monthly mean, 23.4, January; highest daily mean, 81, May 10; lowest daily mean, —1, January 6. *Air pressure* (inches).—Maximum, 30.61, December; minimum, 28.68, February; mean, 29.84. *Precipitation* (inches).—Total (rain and melted snow), 49.87; greatest monthly, 7.44, September; least monthly, 1.48, April; snow fall—total, 59; greatest monthly, 19, March; least monthly, 5, November. *Weather*.—Number of clear days, 131; number of fair days, 112; number of cloudy days, 123; number of days on which 0.01 in. or more of rain fell, 109.

**Report of the meteorologist, T. F. WATSON** (*West Virginia Sta. Rpt. 1896, pp. 249-262*).—A tabulated record is given of tri-daily observations during each month of 1896 on temperature, precipitation, direction of wind, and cloudiness. The following is a summary of the principal data: Maximum temperature, 94° F., August 6, 9, 12;

minimum, 0°, January 5, February 19, 21, 22; mean, 54°; total precipitation, 44.57 in.; melted snow, 7.04 in.; prevailing direction of wind, west.

Weather record for 1896 at Newport, Arkansas (*Arkansas Sta. Rpt. 1897, p. 100*).—Reprinted from Bulletin 46 of the station (E. S. R., 9, p. 630).

### WATER—SOILS.

**Soil moisture**, G. H. FAILYER and J. T. WILLARD (*Kansas Sta. Bul. 68, pp. 75-101, dms. 9*).—This is an account of observations on the moisture content of different kinds of soil treated in different ways at the station and at Garden City and Oakley, Kansas, during the summers of 1895 and 1896. Daily determinations of moisture were made in plowed ground and soil at Garden City from June to September, 1895, and at Oakley during June and July, 1896. At both Garden City and Oakley, the moisture content of plats which had been subsoiled and of those which had not been subsoiled was determined. The effect of salt and gypsum (at rates of 450 and 900 lbs. per acre) on the moisture content of the soil was also tested at Garden City. The experiments at the station included observations in the field on untreated plats and plats treated as follows: (1) Cultivated to a depth of about 5 in. with a hoe; (2) mulched with green grass and sorghum bagasse to a depth of 3 or 4 in.; (3) surface raked to a fine condition to a depth of an inch or more; (4) sown thickly to sorghum broadcast; and observations on evaporation from soils in galvanized iron pails 10½ in. in diameter at the top and 9¼ in. deep. The soils were treated as follows:

“Pots 1, 2, 3, and 4 contained the soil unmixed with other substances. No. 1 was not treated in any way; No. 2 had the soil surface finely pulverized; No. 3 had the soil surface coarsely pulverized; No. 4 was mulched. Pots 5, 6, 7, 8, and 9 were like No. 1, except that No. 5 contained 1 per cent of lime; No. 6, 1 per cent of gypsum; No. 7, one-hundredth of 1 per cent of common salt; No. 8, one-hundredth of 1 per cent of magnesium chlorid; No. 9, 50 per cent of sand.

“In addition to the above pots, we had one numbered 13 which contained soil as in No. 1, but was supplied with water at the bottom by means of a cistern inclosing the bottom of the pail. This cistern was soldered to the pail, could be filled by means of a hole which was closed by a rubber stopper, and communicated with the bottom of the soil through numerous holes over which lay a sheet of blotting paper. The object of this experiment was to observe the rate of evaporation from a soil kept wet by a continuous water supply. Later we added still another, No. 15, which was like No. 9, that is, half sand and half soil, except that it had the continuous water supply as described above. The object in this case was to test further the rate of evaporation from a sandy soil compared with one much less sandy.

“The loss of water was determined by weighing the pots with their contents daily, thus obviating the error that must be inherent to a less or greater degree in any method of field sampling.”

The results of the experiments are given in tables and diagrams. The principal results are summarized as follows:

“In these trials, the undisturbed prairie sod, as compared with that which had been brought under cultivation, was much drier in all cases, except following a heavy rain. In this case, the part sampled of the sod, the upper portion, was about

as wet as the plowed ground, but it rapidly dried out again. The plowed ground, not cropped nor cultivated during the season, was more uniform in its water content than the sod, and was persistently in better condition."

There was no essential difference at the close of the season in the moisture content of a soil which in the previous spring had been (1) plowed shallow, (2) plowed deep, or (3) subsoiled. The results of the tests of the effect of salt and gypsum on moisture content were inconclusive. In a comparison of the loss of water from untreated soil and that cultivated but not cropped, mulched but not cropped, or cropped but not cultivated, the cropped soil dried out most rapidly, the next in order in this respect being the untreated soil. Surface cultivation to a depth of 4 or 5 in. was about as effective in conserving the moisture as the mulch.

"Experiments with soil in galvanized-iron pots, under well-controlled conditions, showed that a layer of finely pulverized soil  $\frac{3}{8}$  in. thick had no marked influence on the rate of evaporation; that a hay mulch 2 in. thick checks evaporation most effectively, but that evaporation proceeds at so rapid a rate from bare soil that a mulch, to be most useful, must be promptly applied; that the rate of evaporation from a sandy soil is less than that from one less sandy when both are kept constantly wet, but if allowed to dry, the sandy soil becomes much drier; that neither salt, gypsum, lime, nor magnesium chlorid exerts any beneficial effect in checking evaporation from the soil, the evaporation being practically the same as from untreated soil."

**Contribution to the study of nitrification in the soil**, T. SCHLOESING, Jr. (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 21, pp. 824-827).—It is stated that nitrification and microbial combustion in general are less active in fine-grained, compact soils than in lighter, coarse-grained soils. This is generally attributed to the greater facility with which the air circulates in the lighter soils and supplies the necessary oxygen.

The author shows that in many cases it is not air but available water which is deficient in the heavy soils.<sup>1</sup> As is well known, the fine particles of heavy soils have so strong an attraction for water that a large part of the soil moisture is rendered unavailable for the growth of the higher plants. It appears from these experiments that it is also rendered unavailable for the use of the nitric ferment. In order that nitrification may be equally active in light and in heavy soils, the latter must have a higher percentage of moisture than the former.

<sup>1</sup> See also Dehérain, *Compt. Rend. Acad. Sci. Paris*, 121 (1895), pp. 30-35.

This fact is brought out in the following results of experiments with artificial soils:

*Nitrification in artificial soils of different composition and water content.*

	Composition of the soil.				Sulphate of ammonia added = nitric nitrogen.	Nitric nitrogen at end of experiment.	Percentage nitrified.
	Sand.	Clay.	Chalk.	Water.			
<i>First series, Jan. 14 to Mar. 27, temperature 26°-27° C.</i>							
	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Mg.</i>	<i>Mg.</i>	<i>Per cent.</i>
Soil No. 1 .....	100	0	0.5	10	40.9	34.1	83
Soil No. 2 .....	90	10	.5	10	40.9	38.5	94
Soil No. 3 .....	80	20	.5	10	40.9	36.2	89
Soil No. 4 .....	75	25	.5	10	40.9	23.5	56
Soil No. 5 .....	70	30	.5	10	40.9	4.23	10
<i>Second series, July 17 to Nov. 1, temperature of laboratory.</i>							
Soil No. 6 .....	100	0	1	9.5	81.8	51.2	63
Soil No. 7 .....	90	10	1	9.5	81.8	54.1	66
Soil No. 8 .....	85	15	1	9.5	81.8	77.1	94
Soil No. 9 .....	80	20	1	9.5	81.8	81.9	100
Soil No. 10 .....	75	25	1	9.5	81.8	17	21
Soil No. 11 .....	70	30	1	9.5	81.8	2.2	2.7
<i>Third series, April 1 to June 12, temperature 26° C.</i>							
Soil No. 12 .....	70	30	.5	10.6	54.5	43.6	80
Soil No. 13 .....	70	30	.5	11.5	54.5	55.9	100

It will be observed that in case of soil No. 11, in which the nitrification was lowest (2.7 per cent), it was only necessary to increase the water content from 9.5 gm. to 11.5 to render nitrification complete. It is evident that it was not air but water which was deficient in the soils containing 25 per cent or more of clay. A very slight increase of water was sufficient to convert almost absolute inactivity into complete nitrification.

**Influence of light, humidity of soil, and depth of cultivation on the position of the stooling node of winter rye, D. N. PRYANISHNIKOV and E. BOARLYUK (*Izv. Moscow Selskokhoz. Inst., 3 (1897), II, pp. 47-49*).**—The experiments were made in 18 cylindrical glass vessels filled with field soil. One half of the vessels had full illumination, while the other half was shaded. Three degrees of humidity were maintained, 30, 55, and 80 per cent of the maximum water capacity of the soil, and the depth of cultivation was about 0.8, 2, and 3 in. In each vessel 10 grains of rye were planted. The results obtained led to the following conclusions: The deeper the grain is seeded the deeper the stooling node, but not in the same degree, since the lowering of the node does not keep pace with the increase of depth of the seed. Shading brings the stooling node nearer to the surface.

These two conclusions relate to the first stooling node. The tendency to form a second node increases with the depth of planting. The position of this second node is strongly influenced by the conditions of illumination, but not by the depth of planting. In regard to the influence

of the humidity of the soil no definite conclusions can be drawn.—  
P. FIREMAN.

**A study of methods of cultivation, J. H. SHEPPERD and J. A. JEFFERY** (*North Dakota Sta. Bul. 29, pp. 185-206*).—An account is given of one year's experiments on 52 quarter-acre and 8 fifth-acre plats at the station to test the relative merits of deep and shallow and fall and spring plowing, subsoiling to different depths, subsurface packing, harrowing after plowing, disking, and the ordinary and Campbell methods of cultivation.

The Campbell method of cultivation is described as follows:

“(1) Plow deeply—7 or 8 in.—preceding the plow with a disk harrow to mellow the surface about to be turned under.

“(2) Follow the plow within a few hours with the Campbell subsurface packer. This machine consists essentially of a series of cast-iron wheels placed abreast upon an iron axle, so that their rims, which are about an inch thick at the base, narrowing to a sharp angle at the extreme circumference, are about 5 in. apart. The whole machine, when run over the soil, is heavily loaded. The object of the subsurface packer is, first, to further pulverize the soil, and second, to bring the newly turned soil, which is held up to a greater or less extent by the stubble, into contact with the bottom of the furrow. This packing of the furrow slice upon the bottom of the furrow renews the capillary relation between the newly turned soil and that below, a thing desirable in a dry fall, and also opens a way downward for rain, should there be any. It is well known that water does not percolate so readily into a soil that is dry and filled with air spaces as it does into one that is already moist, and, while mellow, is not filled with large openings.

“(3) Follow the subsurface packer with a light peg-tooth harrow and harrow the land at intervals thereafter until the crop is sown. This is to keep a shallow mulch over the surface of the ground to retard the evaporation of the moisture into the air.

“(4) Put in all crops so that they may be cultivated. Grains are sown in drills 16 to 24 in. apart.

“(5) Cultivate shallow and often. The Campbell grain drill can be converted into a spring-tooth cultivator, which cultivates the same number of rows that the drill sows. Mr. Campbell's theory is (a) that by this cultivation the loss of moisture into the air is lessened, and (b) that a fewer number of plants with all the moisture they may need will produce a greater yield than more plants with an insufficient supply of moisture.”

Moisture determinations were made by King's method<sup>1</sup> in samples of soil from most of the plats May 24 and August 19 and 20, and from a few of them June 6, and the results with data for cost of production and yields are given in tables.

“In drawing conclusions as to the relative merits of the methods employed in these experiments, it must be remembered that the present year has been one of very unusual conditions, and that future results, under conditions usually prevailing, may be very different from those recorded in this bulletin. Bearing these facts in mind, observe:

“(1) On ground fall-plowed with ordinary plow, (a) the largest average yield was from ground subsoiled 8 in. below a 6-in. furrow. (b) This yield was practically equaled by the average yield from plats packed by Campbell's subsurface packer and cropped in the ordinary way. (c) The highest yields from single plats were from plats subsoiled 8 in. below the bottom of a 6-in. furrow. These were followed

<sup>1</sup> Wisconsin Sta. Rpt. 1890, p. 160 (E. S. R., 2, p. 445).

closely by a plat which was subsurface packed. (d) The sowing of wheat in drills on ground prepared either by the Campbell or by the ordinary method, and cultivated, has not proved a success under prevailing conditions. It has failed to give profitable yields. (e) As between deep and shallow plowing, there stands a slight difference in average results in favor of shallow plowing. (f) The yield of plats 7 and 20 would seem to indicate virtue in fall harrowing.

"(2) The plats plowed and subsoiled with the disk plow leads all other plats with a yield of 26.53 bu. per acre. This was followed closely by the plat which was plowed with a disk plow but not subsoiled.

"(3) On spring-plowed plats, (a) the plats that gave the largest average yield (20.36 bu.) were those which were subsurface packed and sown in the ordinary way. (b) The next best yield came from the plat which was plowed with the disk plow and subsurface packed and sown in the ordinary way. (c) The sowing of wheat in drills, on ground prepared either by the Campbell or other methods, and cultivated, has not given good results. (d) Here, as on the fall-plowed ground, a slight increase of yield was realized on shallow plowing over that on deep plowing.

"(4) Comparing results on fall plowing with those on spring plowing, it will be seen for this year that (a) the subsurface packing of ground immediately after plowing seems to have a very beneficial effect upon yields in both cases; (b) fall subsoiling with a subsoiler to a depth of 8 in. below the bottom of a 6-in. furrow has a beneficial effect upon the next following crop, while spring subsoiling with a subsoiler gave lower yields in the next crop than when the ground was prepared in the ordinary way; (c) fall subsoiling with the disk plow, when followed by the harrow, gave an increased yield, while spring subsoiling with a disk plow lessened the yield; (d) the average yield from shallow plowing, both spring and fall, is slightly larger than that from deep plowing; (e) sowing in drills and cultivating has given reduced yields in every case."

Experiments similar to the above were made in cooperation with the Great Northern Railroad Company at 3 other places in North Dakota, viz, at Lisbon, and 6 miles south of Glen Ullin and 8 miles north of Jamestown, and observations were made at a number of other farms where the Campbell method was being tested under the auspices of the Railroad Company.

The conditions were so different in different cases that definite conclusions are not attempted, but the statement is made that—

"East of the Missouri River, where the weather conditions have been similar to those experienced on the station farm, the results as to yields, so far as reported, have been similar to those obtained at the station. The yield of Campbell-grown grains have been less than those of ordinary grown grain.

"In nearly every case where moisture determinations have been made more moisture was found in the Campbell-worked ground than in that worked by the ordinary method."

## FERTILIZERS.

**Denitrification and farmyard manure**, R. WARINGTON (*Jour. Roy. Agr. Soc. England*, 3. ser., 8 (1897), pt. IV, pp. 577-607).—The author takes exceptions to the conclusions of German investigators (E. S. R., 8, pp. 761, 873) regarding denitrification as due to the action of manure in the soil. He maintains that the denitrifying organisms present in manure, straw, litter, etc., are derived originally from atmospheric dust. Of the conditions necessary to their activity "the supply of organic matter is by far the most important." Figures from Wagner's and Maereker's experiments are quoted to show that the variations in the extent of denitrification in different cases may be explained by variations in the amounts of assimilable organic matter supplied in the manures.<sup>1</sup> Attention is called to the fact, already noted by Dehérain (E. S. R., 8, p. 870), that the amount of manure used in these experiments was far in excess of that ordinarily applied in practice and the results obtained, therefore, furnish "no proof that the same actions will occur to the same extent in ordinary arable farming." This statement is borne out by the results of the Rothamsted field experiments with manure, which are quoted and discussed.

"One fact which comes into great prominence in the German experiments is that ordinary farmyard manure is valueless as food for plants until it is nitrified; this is surely the only conclusion we can draw from the want of action of the manure when applied in large quantities in the pot experiments. In the light of these results the economy of large dressings of farmyard manure becomes very questionable."

**On the substitution of soda for, and its value in connection with, potash**, H. J. WHEELER and G. M. TUCKER (*Rhode Island Sta. Rpt. 1896*, pp. 221-241, pls. 4, dgm. 10).—This is a continuation of investigations carried on since 1894 (E. S. R., 8, p. 579). During the first 2 years of the experiment 2 classes of plants were selected: (1) Those which had given indications that they might be benefited by soda and (2) those which it was thought would not be benefited by it.

"[In 1896, however, it was decided to] conduct the experiments in such a way as to exhaust the assimilable potash from the soil as rapidly as possible in order that any differences which might be attributable to the use of soda might become more strikingly manifest. In order to accomplish this it was planned to grow, if possi-

<sup>1</sup> See also Stutzer, *Dent. Landw. Presse*, 24 (1897), p. 665 (E. S. R., 9, p. 635).

ble. 2 crops per year upon this land until some marked indications of a deficiency of potash might show themselves by those plants which received soda without any addition of potash. . . . In accordance with this plan the 2 crops selected for 1896 were oats and millet, the oats being sown as early as possible and cut while in the milk, so as to enable the millet to enjoy as long a period of growth as possible. . . .

"Dried blood was employed at the rate of 1,020 lbs. per acre or 17 lbs. per plat, dissolved boneblack at the rate of 600 lbs. per acre or 10 lbs. per plat, and finely ground phosphate rock (floats) at the rate of 480 lbs. per acre or 8 lbs. per plat. Each plat received, likewise, magnesium sulphate (Epsom salts) at the rate of 420 lbs. per acre or 7 lbs. per plat. Those plats which received lime in 1894 were again limed in 1896 at the rate of 1,200 lbs. per acre of air-slacked lime or 20 lbs. per plat. Full, three-quarters, half, and quarter rations of the potassium and sodium salts were employed in a similar manner as in the 2 preceding years, the full rations in 1896 being as follows: Potassium carbonate, 360 lbs. per acre, equal to 6 lbs. per plat; sodium carbonate, 240.6 lbs. per acre, equal to 4.01 lbs. per plat; muriate of potash, 394.4 lbs. per acre, equal to 6.64 lbs. per plat; sodium chlorid, 274.2 lbs. per acre, equal to 4.57 lbs. per plat."

Results of the different systems of fertilizing are shown for both crops in tables and diagrams. The results are summarized as follows:

"The inferiority of soda in the absence of potash, as compared with potash in the absence of soda, has become more strikingly manifest from year to year, in each of the 3 years of the experiment. Prior to 1896 the yields were frequently increased by the addition of potash to the full soda ration, and less frequently, if at all, with the addition of soda to the full potash ration. This season, however, in connection with the second crop (millet), the addition of increasing quantities of potash to the full soda ration has increased the crop, in the order of the increased application of potash in each instance. Soda added to the potash ration has this year for the first time given indications of probable usefulness, which, if not incidental, can only become strikingly manifest, if at all, as the depletion of the assimilable potash on the soda plats increases. It would be too hasty to conclude definitely from this year's results that an addition of soda to the potash ration had been positively beneficial, and it may be sufficient at this time to state merely that the results are strongly indicative that such may be the case, a point which it is hoped may be determined in future years."

The results of a comparison on barley and clover of nitrate of potash and of muriate of potash, combined with nitrate of soda, are briefly discussed in this connection. The results of this experiment were not conclusive as to the beneficial or injurious effect of the soda and chlorin upon the plats where muriate of potash and nitrate of soda were used.

**Analyses and valuations of fertilizers,** L. A. VOORHEES and J. P. STREET (*New Jersey Stas. Bul.* 124, pp. 48).—This bulletin gives the trade values of fertilizing constituents in 1897 and the results of examinations of the standard materials supplying them, as well as of home mixtures, factory-mixed fertilizers, and miscellaneous fertilizing substances. Analyses and valuations are given of 75 samples of standard raw materials, 285 samples of brands of complete fertilizers, 16 brands of home and special mixtures, 35 of ground bone, and 36 of miscellaneous products; the materials examined include, in addition to the mixed fertilizers, nitrate of soda, sulphate of ammonia, dried blood, dry ground fish, bone, tankage, dissolved boneblack, dissolved rock phosphates, muriate and sulphate of potash, kainit, double sulphate of

potash and magnesium, marl, garbage fertilizer, mussels, screenings, wool combings, wood ashes, granulated tobacco and sulphur, and tobacco stems.

A study of the results reported will show that—

“while varying considerably in price, nitrate of soda, sulphate of ammonia, and the potash salts are quite uniform in their composition, and comparatively safe to purchase without special chemical examination, although, of course, they should be accompanied by a guarantee. The organic materials, such as dried blood, dried and ground fish, tankage and ground bone, are always more or less variable, and are best purchased with special reference to a guarantee. In a majority of these cases this has been done and the amounts of plant food guaranteed have been delivered to the consumer. The samples of South Carolina rock superphosphate or acid phosphate contain available phosphoric acid in amounts varying from 12.05 per cent to 16.73 per cent, without any decided relation between content and price. To avoid this uncertainty a system of purchase, in which only the amounts actually delivered are paid for, is recommended.”

The results show an improvement in 1897 over previous years in the matter of conforming to guarantees. Eighty per cent of the brands examined contained as much total plant food as guaranteed, 68 per cent reaching or exceeding their guarantees in all particulars, and 40 per cent of the remainder having their deficiencies counterbalanced by an excess in other respects.

The average composition, estimated value, and selling price of all brands of complete fertilizers examined during the year (E. S. R., 8, p. 966) are as follows: Total nitrogen, 2.54 per cent; total phosphoric acid, 10.93 per cent; available phosphoric acid, 8.01 per cent; insoluble phosphoric acid, 2.91 per cent; potash, 5.01 per cent; station valuation, \$21.58; selling price, \$29.28; actual difference, \$7.70; percentage difference, 35.7.

Analyses of 7 samples of home-mixed fertilizers and 9 samples of fertilizers mixed by regular manufacturers specially for their patrons are reported.

“[The results show] that the mixtures were, on the whole, of the composition intended, with the advantage on the side of the manufacturers' mixtures. Many of the guarantees, however, are based upon an estimated analysis of the raw materials. The home mixtures, on the average, cost \$4.38 less, and the manufacturers' mixtures \$0.38 less than their valuation, a difference of \$4, which represents the expenses of mixing, rebagging, etc. In either case there is a decided saving over buying the average fertilizer in the average way, since the selling price of the average complete fertilizer is \$7.70 more than its valuation.”

**Further observations on the growth of various plants upon an acid upland soil, limed and unlimed,** H. J. WHEELER (*Rhode Island Sta. Rpt. 1896, pp. 242-272, pls. 8*).—An account is given of a continuation during 1896 of experiments commenced in 1893 (E. S. R., 8, p. 580). The system of fertilizing has been fully described in previous reports, the same method of fertilizing being used in 1896 as in previous years. No lime has been applied since 1894. The plants experimented with in 1896 included grasses (11 species), blue lupines,

crimson clover, barley, beets, carrots, dandelion, rye, spinach, gladiolus, and various small fruits, orchard fruits, and trees.

"The experiments with grasses show that they vary almost as widely as other plants, so far as concerns the effect of lime upon them. Of the grasses tested, Kentucky blue grass and timothy seem to be most benefited by liming, and Rhode Island bent and redbtop most indifferent to it. Awnless brome grass, meadow oat grass, tall fescue and orchard grass, which are among the most promising of the other grasses tried, all show decided benefit from liming. These results serve to explain why on many of our Rhode Island soils timothy runs out quickly, and redbtop and Rhode Island bent persist better. . . .

"The watermelon seems thus far to be about the only plant frequently grown here which may not be benefited eventually by liming. It is hoped, however, in succeeding years to test this plant more fully.

"Potatoes have sometimes produced a slightly greater total yield from liming and usually a much greater percentage of merchantable tubers, but [lime in the form of] wood ashes and water or air-slacked lime (not gypsum or land plaster) increases the virulence of the potato scab to a serious degree. . . .

"Since potatoes, Indian corn, rye, Rhode Island bent grass, and redbtop are less in need of lime than timothy, clover, barley, etc., certain fields could be set aside for rotations without lime and others with it.

"Beets have shown a wonderful benefit from liming, not only on the station farm, but in many other sections of the State where experiments with them have been tried.

"Spinach has again shown great benefit from liming, it being in this particular like lettuce.

"Rye, dandelions (excepting the first crop in the spring), carrots, and crimson clover have shown a less marked benefit from liming than beets and spinach.

"Lupines . . . are seriously injured by liming.

"In regard to small fruits, orchard fruits, and forest trees little can be said at this time, except that grapes (particularly the Delaware), peach, and elm trees, and quince bushes seem to be benefited by liming. Blackberries were apparently very thrifty on the unlimed sulphate of ammonia plat, where many plants are wholly unable to endure the soil conditions."

A description of the formalin and corrosive-sublimate treatments for potato scab is added.

**Continued observations for the purpose of determining in how far the results secured in a soil test with a given plant are applicable to others, H. J. WHEELER and G. M. TUCKER (*Rhode Island Sta. Rpt. 1896, pp. 273-278*).**—In previous experiments (E. S. R., 8, p. 571) a majority of the crops experimented with indicated a greater deficiency of phosphoric acid than of potash in the soil, while 3 plants, white bean, sunflower, and summer squash, indicated that potash was more deficient than phosphoric acid.

"In order to further test this question the experiment was continued in 1896 with the sunflower, white bean, and crimson clover, and the following crops which had heretofore invariably shown a deficiency of phosphoric acid, namely, Indian corn, millet, and spring rye.

"The results of the experiment this season with the sunflower indicate that the soil was chiefly deficient in phosphoric acid, followed by potash and nitrogen, respectively, or, in other words, was practically in accord with results secured with other plants in previous years. Crimson clover from this year's indications, as well as from those of the 2 previous years, does not seem to be so well adapted as many other

plants for determining the soil requirements, so far as concerns phosphoric acid. The results of the 3 years indicate that out of the 35 plants employed in this soil test (excepting, possibly, crimson clover, white beans, sunflowers, and squashes), almost any one of them would have answered in a satisfactory manner the question as to what element was chiefly deficient in this soil."

**Observations for the purpose of ascertaining if a lack of lime is more or less general in Rhode Island soils,** C. O. FLAGG, H. J. WHEELER, and G. E. ADAMS (*Rhode Island Sta. Rpt. 1896, pp. 282-293, pls. 6*).—This is a continuation of experiments of previous years (E. S. R., 8, p. 580). The effect of lime in connection with other fertilizing materials was tested on barley and beets growing on acid upland soils at 11 different places in Rhode Island.

"The results with barley have shown in a number of instances a benefit from lime, even when it was applied in considerable quantity directly before the sowing of the grain. In 4 instances where the barley was not benefited, it seems probable that such would have been the case had the lime been applied a year before, or had the quantity been much less. In the experiment with beets they were benefited decidedly by liming, in every case but one, the least gain obtained having been 21 per cent, while in other cases the crop was increased 6, 9, 26, and in one case even 100 times." . . .

**Further observations for the purpose of determining whether the beneficial action of lime upon the soil of the experiment station farm is due to any extent to its neutralizing action,** H. J. WHEELER, G. M. TUCKER, and B. L. HARTWELL (*Rhode Island Sta. Rpt. 1896, pp. 294-318, pls. 4*).—An account is given of 5 series of experiments with barley (4) and potatoes (1) grown in pots 18 in. in diameter and 26 in. deep and of 1 series of experiments with barley and clover on field plats. In all experiments phosphoric acid, potash, and nitrogen were supplied in sufficient amounts to meet the requirements of the crops grown, and in different cases caustic lime and magnesia, potassium and sodium carbonates, and wood ashes were used in amounts which insured the same neutralizing effect. Parallel experiments with calcium carbonate and sulphate were also made. The results are tabulated, discussed, and summarized as follows:

"When treated alike in other respects an ill effect from continuous applications of sulphate of ammonia upon the experiment station soil was found to result eventually in all cases, while this was not the case where an equivalent amount of nitrogen in the form of nitrate of soda was employed. The ill effect of sulphate of ammonia can be prevented altogether by the employment in connection with it of sufficient potassium carbonate in place of crude potassium chlorid (muriate of potash) or by the employment of wood ashes, air-slacked lime, sodium carbonate (soda ash), or caustic magnesia. Magnesium sulphate (Epsom salts) was not found equal in this respect to caustic magnesia; the same was true in a more marked degree of calcium sulphate (gypsum or land plaster) as compared with air-slacked lime. Calcium sulphate failed to exert the same beneficial influence upon the growth of potatoes as calcium carbonate, wood ashes, air-slacked lime, calcium acetate, and calcium oxalate; all of which latter substances, if not already composed of or containing calcium carbonate, are changed into that form within the soil.

"These observations lead to the conclusion that aside from a beneficial, manurial, or physical influence which air-slacked lime, wood ashes, calcium carbonate, potas-

sium carbonate, sodium carbonate, and caustic magnesia may have had, they were probably useful, in a high degree, on account of a natural deficiency of bases in the soil, and their ability to correct acidity (sourness) naturally existing or induced therein by artificial methods of cropping and manuring."

**Trial of phosphates, C. O. FLAGG and G. M. TUCKER** (*Rhode Island Sta. Rpt. 1896, pp. 327-343, pl. 1*).—

"The plan of this experiment, commenced in 1894 [E. S. R., 7, p. 851], is to apply the same money value of various materials used to supply phosphoric acid, together with a suitable and like quantity of nitrate of soda and muriate of potash, to 2 series of 10 plats each (including 1 check plat without phosphoric acid), one series limed at the rate of 1 ton per acre at the beginning of the experiment, and the other series unlimed. . . .

"In the fall of 1895, when the plats were seeded to grass, a full ration of the insoluble phosphates—fine ground bone, slag meal, floats, raw alumina phosphate, and ignited alumina phosphate—was applied. [None of] the soluble phosphates—dissolved boneblack, dissolved bone, dissolved phosphate rock (often called acid phosphate) and double superphosphate—were used at time of seeding, but one-third of a full ration was applied each of 3 successive springtimes as a top-dressing. A one-third ration of nitrate of soda and muriate of potash was applied to all the plats. . . .

"The grass in the spring of 1896 showed a much deeper green color throughout the limed series and in the unlimed plats which had received fine ground bone, slag meal, and floats presented the best appearance. The phosphates above named gave the best catch in both series, while dissolved boneblack, dissolved bone, and dissolved phosphate rock were next in rank, giving a fair to good catch in connection with lime, but a very poor one without it. Double superphosphate gave a fair catch with lime and without it a failure. The raw and ignited alumina phosphates and the plat with no phosphoric acid gave the poorest catch in the limed series and without lime a practical failure.

"It is manifestly unfair to judge the efficiency of the various phosphates at this time, because only 3 years have elapsed since the experiment was begun, but especially because the soluble phosphates will not be upon an equal footing with the insoluble until 2 more annual top-dressings have been applied. Judging from the crops produced thus far, they appear to stand in the following order: Fine ground bone, slag meal, floats, dissolved boneblack, dissolved phosphate rock (3 last named about equal), dissolved bone, double superphosphate, ignited alumina phosphate, and raw alumina phosphate, the latter failing to produce as good a crop as the check plat, without phosphoric acid.

"The application of 1 ton of air-slacked lime per acre at the beginning of the experiment in connection with the phosphates has produced a marked beneficial effect, as seen in the general color, growth, and appearance of the crops. The yields have been greater from the limed series than from the unlimed with all the crops grown since the installation of the experiment, the increase due to liming being as follows: Corn crop of 1894 (9 plats), 669.3 lbs. stover, 460.9 lbs. hard corn, and 43.8 lbs. soft corn; oat crop of 1885 (10 plats), 20.25 lbs. of grain and 813.5 lbs. of straw; hay crop of 1896 (10 plats), 1,593 lbs."

**Concerning fertilizers and manures, G. L. TELLER** (*Arkansas Sta. Rpt. 1897, pp. 101-118*).—A reprint of Bulletin 47 of the station (E. S. R., 9, p. 740).

**Fertilizer analyses, R. C. KENZIE** (*Michigan Sta. Bul. 145, pp. 23*).—This bulletin reports analyses of 55 samples of fertilizers examined during 1897, with a schedule of trade values of fertilizing ingredients and a popular discussion of the subject of fertilizers under the following heads: Commercial fertilizers a modern product, names of fertilizers, what do commercial fertilizers contain, results of some analyses,

leading kinds of fertilizers, lime, shall the farmer use commercial fertilizers, are fertilizers stimulants, and how and why are they beneficial, how commercial fertilizers are collected and analyzed, and terms used in reporting fertilizer analyses.

**Analyses of commercial fertilizers and other manurial substances,** C. A. GOESSMANN (*Massachusetts Hatch Sta. Bul. 49, pp. 24*).—Analyses are reported in tabular form of 259 samples of fertilizing materials, including wood ashes, sulphate and muriate of potash, cotton-seed meal, nitrate of soda, sulphate of ammonia, tankage, dry ground fish, ground bone, acid phosphate, South Carolina rock phosphate, mixed fertilizers, cotton waste, hop refuse, spent brewers' grains, sheep manure, muck, compost, soil, and loam.

**Composition of commercial fertilizers,** H. B. McDONNELL ET AL. (*Maryland Sta. Bul. 49, pp. 105-100*).—This bulletin gives a schedule of trade values of fertilizing materials, a list of fertilizers licensed for sale in Maryland for the year ending February 1, 1898, and tabulated analyses and valuations of 390 samples of fertilizers examined during the period from February to July, 1897.

**Commercial fertilizers,** B. H. HITE (*West Virginia Sta. Rpt. 1896, pp. 30-50*).—Analyses and valuations of 478 samples of fertilizing materials are reported.

**How to conduct field experiments with fertilizers,** G. C. CALDWELL (*New York Cornell Sta. Rpt. 1897, pp. 139-147*).—A reprint of Bulletin 129 of the station (E. S. R., 9, p. 339).

**Experiments with artificial fertilizers** (*Vjeskr. Landm., 42 (1897), No. 39, pp. 514-524*).

**Further observations upon the growth of barley upon an acid upland soil, limed and unlimed,** H. J. WHEELER and G. M. TUCKER (*Rhode Island Sta. Rpt. 1896, pp. 279-281*).—Observations upon limed and unlimed acid soil agree with those of previous years (E. S. R., 8, p. 580) and indicate that "on a decidedly acid soil barley may be wonderfully benefited by liming."

## FIELD CROPS.

**Investigations on the influence of factors of growth on the productive capacity of cultivated plants,** E. WOLLNY (*Forsch. Agr. Phys. [Wollny], 20 (1897), No. 1, pp. 53-110, fig. 1*).—A study of the influence of moisture, plant food, and light was made and the results are here reported in tabular form and discussed in detail. Discussions on the influence of temperature and electricity are based upon experiments made by other investigators.

It was found that, in general, grain and root crops reached their highest productive capacity with a smaller percentage of moisture in the soil than legumes and grasses did. The optimum moisture content of the soil for grains and root crops is shown to be from 40 to 60 per cent of the amount of moisture the soil is capable of holding. For legumes the optimum varied between 50 and 70 per cent of that amount and for meadow plants between 60 and 80 per cent.

Experiments were made with different amounts of fertilizer mixtures supplying the necessary elements of plant food in a readily available form to ascertain the influence on plant growth. Rye, peas, rape, sugar beets, potatoes, beans, and corn were grown in pots on sandy, loamy, and peaty soils to which these fertilizer mixtures were applied in quantities differing by a definite amount. The results showed that an increase in plant food does not produce a proportional increase in

yield. The author concludes that the increase of fertilizing material is only profitable within certain limits, and that finally an optimum application is reached which results in a maximum production of plant substance. Beyond this a further increase of available plant food material becomes detrimental to plant growth, due, it is stated, to too great amounts of fertilizing material being carried in solution in the soil moisture, which retard the osmotic action of the roots, thus depriving the plant of its necessary supply of moisture and in consequence causing the turgescence of the cell to decline and in extreme cases to disappear. It was observed that with an increased amount of moisture in the soil larger amounts of the fertilizer mixtures were necessary to retard the growth of the plants.

A study of the influence of light in different degrees of intensity, designated as strong, medium, and weak light, was made; and similar experiments of other investigators are cited in connection with the reported results. It is shown that the productive capacity of cultivated plants both in quantity and quality is dependent upon the intensity of light. In every case plants grown in a strong light were the most productive. The results of experiments made by Briem and Pagnoul are tabulated to show the effect of light on beets and potatoes. Beets grown in the light contained more sugar, and potatoes more starch than those grown in the shade. The author calls attention to the practice of shading crops in tropical climates and concludes that the intensity of light has its minimum, optimum, and maximum, although no exact experiments to determine these points have been made.

A series of experiments was made to ascertain the combined action of water and plant food, light and plant food, and light and moisture. The results indicated that the effect of fertilizers on the productive capacity of plants depends upon the moisture content of the soil to such an extent that the highest absolute yield from the application of fertilizers was obtained with a content of soil moisture corresponding to the optimum; that the applied fertilizer material produced the greatest increase in yield under the strongest light, and *vice versa*; that soil moisture produces its greatest effect upon plant growth when the plants are grown in the strongest light; and that the amount of water needed to produce a maximum yield exerts its full force only when the light passes to the plants unhindered.

No experiments were made by the author to study the effect of temperature on plant growth, but the results are tabulated and discussed of experiments made by Haberlandt, Sachs, and Bialoblocki with the common field crops, on the minimum, optimum, and maximum temperature for germination, the time required for germination, and the rate of growth of the root and plumule at different temperatures.

**Autumn catch crops**, P. P. DEHÉRAIN (*Ann. Agron.*, 23 (1897), No. 12, pp. 561-575).—The results of experiments with vetch and peas as

catch crops in 1897 are reported in tables and the value of legumes for this purpose is pointed out in the discussion. The largest yields were obtained from plats which had received a small application of superphosphates in 1896 and upon which vetch had been grown in 1893. On a number of plats no vetches had been grown, but they had been sown to clover in 1894, and upon these the yields were much better than on plats which had not produced leguminous crops for a number of years. The author states that the quantity of nitrogen in the crops of the best-yielding plats approaches the quantity contained in 13 tons of meadow hay or 36 tons of barnyard manure, and calls attention to the fact that when the necessary moisture conditions prevail autumn catch crops are profitable as forage and green manures.

**Barley—variety tests**, W. W. COOKE (*Colorado Sta. Bul.* 40, pp. 1-11).—The author discusses barley growing in Colorado and describes the hulled and the hullless varieties. It is stated that "Success" barley, a hullless variety, which ripens its grain at an altitude of 7,000 ft. and is grown as a hay crop up to 8,500 ft., has been found profitable. The results of variety tests conducted for 10 years, begun in 1887, are given in tables. The author states that "White varieties of hullless barley have usually produced better than the black or purple, although some yields of the small plats of the purple have been very high." Among the malting varieties Chevalier gave the best results. In 1895 this variety, although lodged flat, yielded over 83 bu. of good solid grain per acre.

**Wheat and barley raising in Denmark**, C. SONNE (*Ugeskr. Landm.*, 43 (1897), No. 43, pp. 571-576).—Of the arable land in Denmark fully 40 per cent is annually sown to the following cereals in the proportions given: Wheat, 5 per cent; rye, 27 per cent; barley, 28 per cent, and oats, 40 per cent. The author summarizes the results of trials with wheat and barley conducted by the Danish State Agricultural Society since 1882, during which about 12,000 plats have been sown to wheat and about 15,000 to barley at trial stations located in different parts of the country. As an average of 1,158 trials on heavy, medium, and light wheat soils, the Squarehead wheat yielded at the rate of 46.3 bu. per acre. This variety, introduced into Denmark in 1874, is now grown on at least 90 per cent of the wheat area of the country, and its introduction is estimated to have increased the yield by at least 10 bu. per acre. The following requirements for obtaining a maximum yield of Squarehead wheat under Danish conditions are the conclusions drawn from extensive culture tests: (1) A rich, clean, and well-drained, preferably loam soil; (2) the sowing of seed wheat of a good quality; (3) sowing in the middle of September; (4) the application of sufficient seed, about 3.4 bu. per acre when sown in drills.

The production of barley is largely for malting purposes. The varieties generally grown are Chevalier, Prentice, and Gold Thorpe. None of these combines in itself the qualities of a good malting barley, as in

one or the other, according to the season or the soil, either the yield or the quality is not all that could be desired. The author considers the requirements for obtaining the best results in the culture of malting barley at some length.—F. W. WOLL.

**Preliminary report upon the selection of potatoes for planting,** H. L. BOLLEY (*North Dakota Sta. Bul. 30, pp. 210-243, figs. 17*).—The present status of the question regarding the form, part, and weight of the tuber piece to be planted is pointed out by citing from the conclusions drawn from experiments made at a number of stations. The influence of variations of varieties upon potato culture is discussed, and the author's work during 3 seasons in the selection of potatoes from the vine and the preparation of the seed are reported and conclusions drawn from the results.

Comparison was made of the growth from large and from small tubers selected from the same vine. In 1894 the tubers were selected from hills of normal growth, which indicated their origin to be from a single piece, and which showed considerable difference in growth, number, size, and form of the potatoes. The peculiarities of tubers from each hill were noted. Small tubers were selected from those weighing between 1½ and 2 oz. and the large ones from those exceeding 6 oz. in weight. "The specific gravity of each tuber was then taken, which was found to be essentially the same for large and small tubers from the same hill, but often very different in different hills." After receiving the corrosive sublimate treatment for the prevention of scab one piece, an ounce in weight, was taken from the bud end of each selected tuber. These pieces were planted in the spring of 1895 3 ft. apart each way and 4 in. deep, with the cut surface down. Only one piece was planted in a hill. Soil condition and cultivation were as nearly alike for the entire crop as it was possible to make them. For this season the average weight per hill of the product in tubers grown from the small tubers at the time of digging was 2.1467 lbs. and the average weight per hill for those grown from large tubers was 1.92 lbs.

The tubers from most of the hills were planted the next season (1896) with the preparation already described. The hills from which no seed was planted in 1896 were those which had produced only large or only small tubers. The average yield per hill in 1896 was 26.54 oz. for those planted with pieces of small potatoes and 25.45 oz. for those planted with pieces of large potatoes, a difference of 1.09 oz. per hill in favor of the small potatoes. In 1897 work was continued, but weather conditions made the crop of no value for the details of comparison.

The author concludes from the results that "the weight of the piece has very little to do with the number of stalks which appeared in the hill," and adds that he is inclined to attribute the variability in the number of stalks produced from the pieces of like weight and pedigree chiefly to conditions affecting the vigor of first growth of the sprouts.

It was found that the number of tubers per hill increased quite regu-

larly with the number of stalks produced. "The conclusion is that, with a comparatively stable strain, any condition which results in an increase of stalks per hill will likewise result in a nearly proportionate increase of tubers per hill."

In summarizing the observations of the 3 years the author makes the following statements:

"Because of the tendency of potatoes to vary under cultivation, and because such variations tend to run into certain strains, some valuable and others comparatively valueless, it is evident that the selection of proper tubers for planting is the first essential to culture. This selection should be done in the field at digging time, and should be made from those hills which produce potatoes of the form and character desired.

"In planting equal weight pieces from small and large tubers of the same vine there will not be a sufficient difference in favor of one or the other size of potatoes to be noticed under farm methods, provided all are normally mature."

**Further tests of northern and home grown seed potatoes, C. O. FLAGG and G. M. TUCKER** (*Rhode Island Sta. Rpt. 1896, pp. 344-353*).—A continuation of work reported in a former bulletin of the station (E. S. R., 8, p. 217). This was the third year that seed tubers were obtained from Maine to compare northern and home grown seed. In general, the same varieties were brought from Maine each year and grown in Rhode Island for 2 and 3 years in succession. Tabulated results show the degree of maturity and the average yields, weights, and number of tubers obtained.

The averages for all the varieties of Maine seed grown at the station 1, 2, and 3 years are given in the following table:

*Yield from Maine potatoes grown in Rhode Island 1, 2, and 3 years.*

	Average weight of—			Proportion of large tubers.		
	All tubers.	Large tubers.	Small tubers. <sup>1</sup>	1896 by number.	1896 by weight.	1895 by weight.
	<i>Pound.</i>	<i>Pound.</i>	<i>Pound.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
From seed grown 1 year.....	0.135	0.27	0.10	22.17	43.05	72.77
From seed grown 2 years.....	.120	.25	.09	20.25	35.84	69.45
From seed grown 3 years.....	.120	.25	.10	19.45	38.41	.....

<sup>1</sup>In 1896 all tubers weighing 3 oz. or more and in 1895 those weighing 2 oz. or more were classed as large tubers.

In summarizing, the authors state that the total yield of the northern-grown seed was 28.42 bu. per acre less the first year than for seed grown at the station for 2 years, and 17.02 bu. less than from seed grown at the station 3 years, but that the increase in the crop from the home-grown seed consisted of tubers less than 3 oz. in weight.

"The yield of tubers 3 oz. or more in weight was 1.29 bu. greater than the home-grown second-year seed and 2.21 bu. per acre greater than was obtained from the home-grown third-year seed."

The more important cultivated plants of German colonies and their products, R. SADEBECK (*Die wichtigeren Nutzpflanzen und deren Erzeugnisse aus den deutschen Kolonien. Hamburg: Lucas Gröfe & Sillem, 1888, pp. 138*).

**Forage crops**, I. P. ROBERTS and L. A. CLINTON (*New York Cornell Sta. Rpt. 1897*, pp. 271-296, figs. 6).—A reprint of Bulletin 135 of the station (E. S. R., 9, p. 341).

**Jackson Limbless cotton**, R. J. REDDING (*Georgia Sta. Press Bul. 36*, pp. 2).—A report on a test of 21 varieties of cotton, including the so-called Jackson Limbless. The author describes the merits of this variety. He believes it to be identical with Welborn Pet.

**Potato culture**, I. P. ROBERTS and L. A. CLINTON (*New York Cornell Sta. Rpt. 1897*, pp. 151-163, figs. 4).—A reprint of Bulletin 130 of the station (E. S. R., 9, p. 343).

**The sugar beet**, H. J. WATERS (*Missouri Sta. Bul. 40*, pp. 16, fig. 1).—This bulletin contains a tabulated report of the cooperative experiments with sugar beets in 1897. From 90 counties 304 samples were obtained and analyzed. The average weight of the beets in the samples was 26 oz., the average percentage of sugar in the juice 11.14, and the average coefficient of purity 71. Of the samples analyzed 117 contained 12 per cent or more of sugar in the juice. These samples were furnished by 73 counties. Notes are given on previous experiments in this line and on the weather conditions for the season of 1897.

**Distribution of seeds and plants**, E. J. WICKSON (*California Sta. Bul. 118*, pp. 8).—Brief reports are given of the seeds and plants distributed by the station and descriptions and lists given of those offered for distribution during the coming season.

## HORTICULTURE.

**Latitude and plant growth**, L. C. CORBETT (*West Virginia Sta. Rpt. 1896*, pp. 178-193, pls. 1).—This is an extract from a thesis on this subject. Instances of the effect of climate on the growth of grapes, Russian apples, and corn are noted, and the results of experiments with cuttings and seeds of various plants are given.

In 1889-'90 cuttings of Concord grapes from New Jersey, Virginia, and New York were compared, all having received the same treatment after the experiment began. The New York cuttings started growth earlier than the others and a greater percentage of them grew. Fay Prolific and White Grape currant cuttings from New York and New Jersey showed practically no difference, either in time of starting or in vigor of growth. Cuttings of poplar, 24 from New York and 24 from Virginia, were planted at the same time and given the same treatment. Two weeks after planting all the New York cuttings, but none of the Virginia cuttings, had started growth. At the end of 3 weeks 11 of the Virginia cuttings had started. About 6 weeks after planting all of the Virginia cuttings had started, but the New York cuttings were then at least one-third more advanced. In the case of Meech Prolific quince, 6 out of 14 cuttings from New York and only 1 out of 14 from New Jersey had started growth 2 weeks after planting. Of the Orange quince 7 out of 11 cuttings from New York and none of the 9 cuttings from New Jersey had started 2 weeks after planting.

In 1891-'92, 37 cuttings of Lombardy poplar from Maine were compared with 39 cuttings from New York. About 6 weeks after planting the Maine cuttings had made an average growth of 1.96 in. and the New York cuttings 1.64 in. A comparison was made of 30 cuttings of the Concord grape from Maine, 32 from New York, and 23 from Louisiana.

About 6 weeks after planting, the Maine cuttings had made an average growth of 2.66 in., the New York cuttings 1.6 in., and the Louisiana cuttings 1.3 in. The difference in the growth of the grape and poplar cuttings from different States is shown in plates.

Potatoes from Maine and New York were grown under like conditions in a greenhouse. Crane June Eating potatoes of New York stock and grown for a single season in Maine were compared with others of the same stock grown continuously in New York. Similarly, Early Rose potatoes of Maine stock and grown in New York but a single season previous to the experiment were compared with others of the same stock grown continuously in Maine. Little difference was observed in the rapidity of germination in either case between the Maine and the New York potatoes. In both cases the plants from tubers grown in Maine had much darker green foliage, grew larger, and yielded a larger crop than plants from tubers grown in New York. The increased yield was shown in the greater size rather than in the greater number of tubers produced.

A number of experiments on the germination of seeds of various varieties of corn, beans, and watermelons grown in the North and the South are quoted from a thesis presented to Cornell University by Messrs. Royce and Atwood. The results indicated that northern-grown seeds germinate somewhat more rapidly than southern-grown ones.

The author believes that these experiments are sufficient to establish the superiority of northern-grown seeds, potato tubers, and hard-wood cuttings, a northern climate having a tendency to hasten development and increase yield.

**Mixed graftage**, L. DANIEL (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 18, pp. 661-664; also in *Rev. Hort.*, 69 (1897), No. 24, pp. 566-568, and *Bul. Mens. Soc. Cent. Agr., Hort. et Acclim.* [Nice], 37 (1897), No. 12, pp. 229-233).—The author describes a method which he calls mixed graftage (*la greffe mixte*), and reports some experiments comparing it with the ordinary method. The method differs from the ordinary method in that a few shoots are allowed to grow permanently upon the stock and are kept pruned sufficiently to prevent their seriously checking the growth of the scion.

By means of mixed graftage a successful union of a scion of the wild cherry (*Cerasus avium*) with the cherry laurel (*Prunus lauro-cerasus*) as a stock was readily effected, a union which is considered very difficult to secure on account of the widely different characteristics of the 2 trees, one having deciduous and the other persistent leaves.

In order to compare the effect of ordinary graftage with that of mixed graftage, 2 very unlike haricots, the large haricot of Soissons and the black Belgian haricot, were used. In case of both methods of graftage the black Belgian haricot was used as the scion and the large haricot of Soissons as the stock. The grafted plants were grown together with nongrafted ones of both sorts under the same conditions

of soil and exposure. The large haricot of Soissons grew to a height of 450 cm., had many large leaves, long racemes of some 20 yellowish-white flowers, producing from 3 to 5 fruits with white seeds; the fruit had a decidedly disagreeable taste. The black Belgian haricot grew to a height of 40 cm., had numerous leaves and short racemes of 3 to 5 violet-colored flowers, producing from 2 to 3 fruits with dark violet seeds; the fruit was tender and of a very agreeable taste.

The plants resulting from ordinary graftage of the black Belgian haricot on the large haricot of Soissons grew to be 25 cm. high, had fewer and lighter green leaves than the nongrafted black haricot, and racemes of 2 to 3 violet-colored flowers, producing 1 to 2 fruits with dark violet seeds. The fruit had a taste resembling somewhat that of the large haricot of Soissons. The plants resulting from mixed graftage of the black Belgian haricot upon the large haricot of Soissons were 40 cm. high and had leaves like the nongrafted black haricot. Some of the flowers were of a violet color, others variegated white and violet; 1 raceme was long, having 9 variegated flowers, producing 3 fruits, and the other racemes were short like those of the black Belgian haricot. The fruit had a taste decidedly like that of the large haricot of Soissons; and the seeds were of a dark violet color.

Some of the conclusions which the author draws from these experiments are: Mixed graftage should be used with plants presenting any marked differences, as those between deciduous and evergreen trees. The stock does not influence the scion in the same way in cases of mixed graftage as of ordinary graftage. Such characteristics as may be attributed to variations of environment (height, vigor, resistance to parasites, etc.) are affected less by the stock in the case of mixed graftage than of ordinary graftage. On the other hand, characteristics peculiar to the variety of the stock (flavor, form of fruits, color of flowers, etc.) mix with those of the scion much more readily with mixed than with ordinary graftage.

**Vegetables**, L. C. CORBETT (*West Virginia Sta. Bul. 19, pp. 467-507, figs. 2*).—The bulletin reports culture and variety tests of a number of vegetables.

A test of hill *vs.* drill planting of beans resulted in favor of drill planting; 2 lbs. of seed planted in drills yielded a product of 140.4 lbs., while the same quantity of seed planted in hills yielded a product of only 50.7 lbs. A similar test made by the author in South Dakota is quoted (*E. S. R.*, 8, p. 790). Large White Lima beans were planted on inverted sods in the greenhouse March 27, April 3, and April 10, and in the open May 7. The largest yield was obtained from the planting of April 3, the next largest from that of April 10, and the smallest from the May planting. A tabular statement of the yield of 6 varieties of bush beans and 4 varieties of bush Lima beans is given.

A test was made of planting peas at depths of 2, 3, 4, 6, and 8 in. Peas planted 3 in. deep gave the highest percentage of germination

and a greater yield than those planted at other depths. The time of maturity was not materially affected by the depth of planting. In the fertilizer test with tomatoes, sulphate of potash, muriate of potash, bone meal, and nitrate of soda were used singly and in various combinations. The use of nitrate of soda alone gave the smallest yield and the fewest fruits per plant. Bone meal gave the best results of any single fertilizer and sulphate of potash the next best. Sulphate of potash proved much superior to muriate of potash, both when used alone and when used in combination with nitrate of soda. Of the various combinations of fertilizers a mixture of equal parts of the 4 fertilizers used gave the best results.

Tomatoes pruned after the fruit set produced a greater number of ripe fruits per plant up to September 1 than unpruned plants, but the total yield per plant for the whole season was less. Of the various methods of pruning tomatoes, the single-stem method gave somewhat earlier and larger fruits, but lessened the total yield considerably. Tomatoes trained on racks gave a larger yield than on any other kind of trellis.

Seed of Dwarf Champion tomatoes was sown at intervals of 10 days from February 10 to April 10. The largest crop was obtained from seed sown about March 1.

The use of a straw mulch increased the yield of tomatoes and decreased the amount of rot, the average weight of fruit per plant being 14.6 lbs. in case of the mulched plants, and 12.2 lbs. in case of the plants without mulch, and the percentages of rot 0.97 and 1.88, respectively.

Various methods of handling tomato plants previous to setting them in the field were tested. Part of the plants were left in the seed bed until ready to be planted in the garden and were then set in the soil with a dibble. Another lot of plants was treated in the same way, except that they were set in holes previously dug for them. The third lot was transplanted from the seed beds to flats, later transferred to other flats, and when removed to the field holes were dug for them. A fourth lot was treated like the third, except that the plants were transplanted from the first flat to 1-quart vegetable cans. A fifth lot was also treated like the third, except that the plants were set in the garden with a dibble. A sixth lot was transplanted from the seed bed into 2-inch pots, transferred to 3½-inch pots, and when set in the garden holes were dug for them. The plants from pots gave the best results and those from vegetable cans next best. The difference between the other methods was not very great. The author considers the increased yield due to growing young plants in pots sufficient to repay the extra expense made necessary by the use of pots.

A test of tomato cuttings *vs.* seedlings for forcing house culture resulted decidedly in favor of the seedlings. From experiments with seedlings and cuttings for outdoor culture, the author concludes that cuttings give more, earlier, and smaller fruit than seedlings.

The results of a test of a number of varieties of tomatoes are reported in tabular form. The excessive rainfall of July caused irregularities in the setting of fruit. From the test the author concludes that "large size in fruits is incompatible with great numbers," and that "the greatest yield in bushels is to be expected from plants producing fruits of medium large size."

**Apples**, L. C. CORBETT (*West Virginia Sta. Rpt. 1896, pp. 199-215, pls. 15*).—This is a popular article discussing the adaptability of West Virginia to apple growing, the orchards of northern West Virginia, the management of orchards, the packing and care of fruit, the longevity of fruit trees, etc.

In regard to pruning the author urges that the method used be made to correspond to the peculiarities of the variety, rather than that a particular method be used in all cases. For instance, in case of the King and Willow varieties of apples, which bear a large part of their fruit near the outer ends of their long, slender, decumbent branches, heading-in should be practiced. On the other hand, with such varieties as Ben Davis and Baldwin apples, which have a more compact form and a better distribution of fruit, thinning the branches should be practiced.

Instances are cited to show the effect of top grafting and root grafting on the longevity of some varieties of fruits. Trees of the King apple, top worked on seedlings and now 20 years old are in fairly good condition, while others of the same variety, root grafted and set in the same orchard at the same time, have been dead for 10 years. Ten top-grafted and 10 root-grafted Walldow apples were set in an orchard at the same time. The top-worked trees at the age of 20 years are living and thrifty, while of the root-grafted trees only one limb of one tree is living, the majority of the trees having died between the ages of 5 and 10 years. In an apple orchard planted with 100 root-grafted and 70 top-grafted trees, 44 per cent of the former and only 7.2 per cent of the latter have died. In propagating varieties of apples that have weak trunks, top grafting or, even better, double working is recommended. For double working, Tolman Sweet is considered a good variety, since "it possesses a close, smooth bark, a strong yet not rapid growth, and a great length of life."

**Strawberries**, J. T. STINSON (*Arkansas Sta. Bul. 48, pp. 119-140, figs. 5*).—The bulletin gives general information on strawberry growing in the State and the results obtained at the station. Descriptive notes are given on 43 varieties of strawberries grown at the station and on 23 varieties grown in other parts of the State. A summary of results reported in previous publications of the station is given, and the varieties which have since been discarded are noted.

The culture of strawberries is discussed in a popular way, preparation of soil, setting plants, perfect and imperfect varieties, cultivation, mulching, renewing old beds, implements, crates for marketing, and

the like being considered. Mulching strawberry beds was found to increase the yield of fruit fully one-third. A portion of each row of about 50 varieties were mulched and a portion of each row left unmulched. The yield was increased by mulching in every case, but the increase varied considerably with the different varieties, being greatest with the large-fruited and medium to late varieties.

**Vine pruning**, F. T. BIOLETTI (*California Sta. Bul. 119, pp. 16, figs. 11*).—This is a popular bulletin discussing the principles and methods of grape pruning and training adapted to California conditions. The discussion is based upon experiments at the station, observations throughout the State, and a study of foreign methods.

The bulletin states 8 physiological principles connected with pruning and training, describes a typical vine, and gives the names of the different parts, discusses pruning for wood and for fruit, shows the method of making the cut in pruning, describes and illustrates several systems of pruning and training and gives a list of varieties adapted to each system, discusses various modes of summer pruning, and the like. The kind of treatment to be given in any case depends upon the habit of growth of the variety and upon the fertility of the soil.

**Extension work in horticulture**, L. H. BAILEY (*New York Cornell Sta. Rpt. 1896, p. 161-206*).—A reprint of Bulletin 110 of the station (E. S. R., 8, p. 135).

**Second report of extension work in horticulture**, L. H. BAILEY (*New York Cornell Sta. Rpt. 1896, pp. 533-564, figs. 14*).—A reprint of Bulletin 122 of the station (E. S. R., 8, p. 790).

**Dwarf apples**, E. G. LODEMAN (*New York Cornell Sta. Rpt. 1896, pp. 376-404, figs. 5*).—A reprint of Bulletin 116 of the station (E. S. R., 8, p. 226).

**Fig caprification**, N. B. PIERCE (*California Fruit Grower, 22 (1898), No. 10, p. 4*).

**Green crops in orchards**, L. F. KINNEY (*Rhode Island Sta. Rpt. 1896, p. 188*).—A brief note on the use of crimson clover and cowpeas in orchards.

**Lemon growing and curing**, W. S. WILLIAMS (*Queensland Agr. Jour., 1 (1897), No. 6, pp. 444-447*).

**Japan plums**, E. O. ORPET (*Amer. Gard., 19 (1897), No. 163, p. 110*).

**Revised opinions of Japanese plums**, L. H. BAILEY (*New York Cornell Sta. Rpt. 1896, pp. 39-67, figs. 13*).—A reprint of Bulletin 106 of the station (E. S. R., 8, p. 50).

**Notes upon plums for western New York**, S. D. WILLARD and L. H. BAILEY (*New York Cornell Sta. Rpt. 1897, pp. 167-195, figs. 12*).—A reprint of Bulletin 131 of the station (E. S. R., 9, p. 351).

**Raspberries**, L. C. CORBETT (*West Virginia Sta. Bul. 48, pp. 454-464, figs. 4*).—A popular article read before the West Virginia State Horticultural Society. It treats of propagation, planting, pruning, cultivation, harvesting, evaporating, construction of evaporators, etc.

**Why not grow raspberries?** L. C. CORBETT (*West Virginia Sta. Rpt. 1896, pp. 215-225, figs. 4*).—A reprint of Bulletin 48 of the station (see above).

**Raspberry culture**, E. F. AUGUSTINE (*Canad. Hort., 21 (1898), No. 3, pp. 90-94, figs. 6*).—A reprint from Ontario Farmers' Institute Report for 1897.

**Strawberries**, F. T. STINSON (*Arkansas Sta. Rpt. 1897, pp. 119-140, figs. 5*).—A reprint of Bulletin 48 of the station (see p. 918).

**Strawberries under glass**, C. E. HUNN and L. H. BAILEY (*New York Cornell Sta. Rpt. 1897, pp. 261-268, figs. 2*).—A reprint of Bulletin 134 of the station (E. S. R., 9, p. 353).

**Chestnut possibilities in Pennsylvania** (*Pennsylvania Dept. Agr. Rpt. 1896, pp. 410-414*).

**Outlines of agricultural and horticultural work**, L. C. CORBETT (*West Virginia Sta. Rpt. 1896, pp. 165-175, 244-248*).—The work done during 1896 and experiments to be made during 1897 are noted. A list of donations to the horticultural department in 1896 is given.

**A "mixed" method of grafting** (*Gard. Chron., 3. ser., 23 (1898), No. 580, p. 84*).—A review of the work of Daniel (E. S. R., 9, p. 945).

**Cuttage**, S. MOTTET (*Rev. Hort., 70 (1898), No. 2, pp. 41-45, figs. 9*).—Some of the physiological principles concerned in cuttage are noted.

**Cuttage**, L. C. CORBETT (*West Virginia Sta. Rpt. 1896, pp. 175-178*).—An extract from a thesis on this subject. It discusses the importance and necessity of cuttage.

**The 1895 chrysanthemums**, L. H. BAILEY, W. MILLER, and C. E. HUNN (*New York Cornell Sta. Rpt. 1896, pp. 259-292, figs. 12*).—A reprint of Bulletin 112 of the station (E. S. R., 8, p. 130).

**Chrysanthemums in 1896**, L. H. BAILEY and W. MILLER (*New York Cornell Sta. Rpt. 1897, pp. 300-320, figs. 8*).—A reprint of Bulletin 136 of the station (E. S. R., 9, p. 356).

**Subirrigation for chrysanthemums**, L. R. TAFT (*Amer. Florist, 13 (1898), No. 510, pp. 881, 882*).

**The cistuses** (*Garden, 53 (1898), No. 1369, pp. 130-132, figs. 5*).—Cultural and descriptive notes.

**A talk about dahlias**, W. MILLER (*New York Cornell Sta. Rpt. 1897, pp. 99-136, figs. 9*).—A reprint of Bulletin 128 of the station (E. S. R., 9, p. 339).

**Hyacinth propagation**, S. B. DICKS (*Florists' Exchange, 10 (1898), No. 11, p. 270, figs. 3*).

**The Nepenthes and their culture; a botanical and horticultural study of the Nepenthes**, J. RUDOLPH (*Les Nepenthes et leur culture; étude botanico-horticole sur les Nepenthes. Paris: Octave Doin, 1896, pp. 31, figs. 5*).

**Exotic orchids and their culture in Europe**, L. LINDE~~x~~, A. COGNIAUX, and G. GRIGNAN (*Les orchidées exotiques et leur culture en Europe. Paris: Octave Doin; Brussels: L. Linden, A. Cogniaux, and G. Grignan, 1894, pp. 1019, figs. and pls. 141*).—The work is divided into 4 parts. The first part treats of the classification and geographical distribution of orchids, with a bibliography of the subjects. The second part has to do with the history of the cultivation of orchids, their habitat, and the importation of them. The third part discusses in detail the culture of orchids in Europe. The fourth part gives descriptions of the principal orchids grown in Europe.

**Dictionary of hybrid orchids**, E. BOHNHOFF (*Dictionnaire des orchidées hybrides. Paris: Octave Doin, 1895, pp. 139*).—The first part of this book contains an alphabetical list of all artificial and natural orchid hybrids known to the author up to the year 1895, the name of the originator or introducer of each, the date of its introduction, and the names of its seed-parent and pollen-parent. The second part of the book gives tables to facilitate finding the parentage and synonyms of hybrids, etc. The title-page, preface, and all explanations of tables are given in French, German, and English.

**Tufted pansies**, D. B. CRANE (*Garden, 53 (1898), No. 1370, pp. 148, 149, pl. 1, figs. 2*).

**Zonal pelargoniums as pot plants**, H. SHOESMITH (*Garden, 53 (1898), No. 1370, pp. 154, 155*).—Notes on culture and propagation.

**Sweet peas**, L. H. BAILEY and A. P. WYMAN (*New York Cornell Sta. Rpt. 1896, pp. 211-253*).—A reprint of Bulletin 111 of the station (E. S. R., 8, p. 131).

**A second account of sweet peas**, A. G. WYMAN and M. G. KAINS (*New York Cornell Sta. Rpt. 1897, pp. 63-95, figs. 2*).—A reprint of Bulletin 127 of the station (E. S. R., 9, p. 356).

**Water cress: Its history and cultivation**, W. W. GLENNY (*Garden, 53 (1898), No. 1369, pp. 124-126*).—Taken from the Journal of the Royal Agricultural Society of England.

**Suggestions for the planting of shrubbery**, L. H. BAILEY (*New York Cornell Sta. Rpt. 1896, pp. 502-529, figs. 29*).—A reprint of Bulletin 121 of the station (E. S. R., 8, p. 495).

**Hints on formed trees**, F. JAEKEL (*Pennsylvania Dept. Agr. Rpt. 1896, pp. 558-568, figs. 11*).—Various modes of training fruit trees are described.

**Trees to adorn streets**, W. R. SMITH (*Florists' Exchange, 10 (1898), No. 10, pp. 240, 241; Amer. Florist 13 (1898), No. 509, pp. 845, 846*).—An address before the Massachusetts Horticultural Society.

**Moisture the plant's greatest requirement**, J. C. ARTHUR (*Amer. Florist*, 13 (1898), No. 508, pp. 813, 814; *Florists' Exchange*, 10 (1898), No. 9, pp. 215, 216, fig. 1; *New England Florist*, 4 (1898), No. 1, pp. 3-5).—A paper read before the American Carnation Society at Chicago. It deals with the water requirements of plants, with special reference to carnation culture. The author believes that a constant stream of water through the plant is required for healthful development and recommends that carnations be grown in an atmosphere sufficiently dry to insure considerable evaporation from their leaves and that, to keep the air from becoming too moist, subwatering be practiced. Other advantages of subwatering are also noted.

**McGregor's new book on growing flowers**, MCGREGOR BROS. (*Springfield, Ohio: McGregor Bros.*, 1897, pp. 104).—A book of practical suggestions on the care and management of flowers in the house and garden, with culture directions for such plants as require special treatment.

## FORESTRY.

**Afforestation of abandoned fields on the Biltmore estate**, C. A. SCHENCK (*Forester*, 4 (1898), No. 4, pp. 78-80).—A report is given of the cost of planting in the fall of 1897 about 45 acres of abandoned fields on the Biltmore estate. These fields had been exhausted or the slope of the ground was too steep to permit of profitable use for field crops or pasturage. The varieties of seed planted were walnut, buckeye, white oak, chestnut oak, hickory, red oak, and chestnut. The total expense of the planting, except that of the salary of the ranger who superintended the work, and allowance for wear and tear of tools is given.

The white and chestnut oak seeds were planted 4 in. apart in the rows, the buckeye and red oak 8 in., and the walnut and hickory 12 in. The rows were 3 to 4 ft. apart, according to the slope of the ground, those on the steep slopes being a wider distance apart so as to allow cultivation without injury to the seedlings. The aggregate expenses are said to be higher than necessary under ordinary conditions of afforestation, as there was a desire for quick results.

In order to check the ravages of field mice it was necessary to cultivate the different plantations about four times at a cost of about 40 cts. per acre. After about the third growing season the roots of the seedlings will be strong enough to offer resistance.

The cost of planting an acre varied from \$5.70 in the case of chestnuts to \$16.20 in one of the white oak plantations. However, the author states that the average cost should not exceed \$12 per acre.

Assuming that the plantations will be ready for cutting within 100 years, and placing a fair estimate upon the present value of the land, taxes, administration, etc., the author states that the indications are favorable to a production which will represent  $2\frac{1}{2}$  per cent compound interest on the investment. This would require a stumpage of about 40,000 B. M. per acre. In addition to the yield of lumber there will be immediate returns in the way of firewood, tan bark, fence posts, seeds, etc., which will render the interest on the capital invested considerably higher than the amount stated.

**Trees from South Asia acclimated in southern California, I, F. FRANCHESCHI** (*Forester, 4 (1898), No. 4, pp. 76, 77*).—The author calls attention to a number of species of Eucalyptus, Acacia, Grevillea, Casuarina, Araucaria, etc., which have not only become well established in southern California, lending their peculiar features to the landscape, but have also become of very considerable economic value, the Eucalyptus furnishing the chief supply of fuel for that region. In addition to these Australian trees the following from South Asia have shown themselves adapted to the conditions found in southern California: *Michelia champaca*, *Flacourtia ramontchi*, *Pittosporium nilghirense*, *Kayea eugeniaefolia*, *Gordonia anomala*, *Hibiscus rosa sinensis*, *H. mutabilis*, *Kydia calycina*, *Reeresia thyrsoides*, *Berrya ammonilla*, *Murraya exotica*, *Glycosmis pentaphylla*, *Clauseria wampi*, *Garuga pinnata*, *Bursera serrata*, *Melia azedarach*, *Aglaiia odorata*, *Cedrela toona*, *C. serrata*, *Euonymus tingens*, *Hovenia dulcis*, *Sapindus utilis*, and *Nephelium lit-ehi*.

**The reforestation of the sand hills of Nebraska, C. E. BESSEY** (*Nebraska State Bd. Hort. Rpt. 1897, pp. 38-44, map 1*).—The author describes the general characteristics of the sand-hill region of the State. This region, which embraces from 15,000 to 20,000 square miles, the author thinks possible to reforest in the following manner: "The setting apart of large areas for forests by the General Government, which still owns a greater part of the land of this region; the stoppage of prairie fires over this region; inclosure of the lands so as to exclude herds of cattle; the planting of small areas scattered over these forest tracts with hardy shrubs and trees of rapidly spreading kinds; the careful supervision of these forest areas by competent keepers."

**The effects of Arbor Day upon economic forest planting, J. STERLING MORTON** (*Forester, 4 (1898), No. 4, p. 72*).

**Park management and forestry** (*Forester, 4 (1898), No. 4, pp. 73, 74*).

**Essentials in park planting, W. H. MANNING** (*Forester, 4 (1898), No. 4, pp. 74, 75*).

**Forest seed selection, C. A. KEFFER** (*Forester, 4 (1898), No. 4, pp. 77, 78*).

**Forestry in Virginia, J. GIFFORD** (*Forester, 4 (1898), No. 4, pp. 80-82*).

**Forest destruction and waterflow, southern California, II, A. KINNEY** (*Forester, 4 (1898), No. 4, pp. 82, 83*).

**An old plantation of Pinus strobus, LOREY** (*Allg. Forst u. Jagd Ztg., 74 (1898), No. 2, pp. 43-45*).—Compares the growth of white pine with fir, hemlock, etc., of known age.

**Degrees of thinning forests, A. C. FORBES** (*Gard. Chron., 3. ser., 23 (1898), No. 581, pp. 97, 98*).

**Fire wounds, L. C. CORBETT** (*West Virginia Sta. Rpt. 1896, pp. 226-235, pl. 1*).—The author discusses the injurious effects of forest fires and the value of second-growth timber which springs up after the original forest has been destroyed.

## SEEDS—WEEDS.

**Investigations concerning the methods of seed testing, especially of grass seed, R. HARTLEB and A. STUTZER** (*Jour. Landw., 45 (1897), No. 1, pp. 43-60, figs. 2*).—The authors criticise the official regulations for seed testing,<sup>1</sup> and suggest various sources of possible

<sup>1</sup> Landw. Vers. Stat., 47 (1896), p. 231.

error. The kind of seed bed, ventilation, evolution of oxygen, temperature, light, and duration of the test are all stated as of great importance in seed testing.

The methods for purity examination are considered at considerable length and a form of apparatus designed to assist in this determination is figured and described.

The kind of seed bed, especially when testing grass seeds, is shown to be of great importance, examples being quoted in which the germination of samples of grass seed averaged 66 per cent for the Nobbe apparatus, 91 for filter paper, and 44 for open earth.

The influence of temperature on germination is shown. For some grasses, as well as for beet, carrot, and other seed, a constant temperature of 30° C. seems to be the best. This is in direct opposition to the regulations of the German Seed Control, as they recommend 30° C. for 6 hours daily, after which the thermostat is to be kept at about 20° C. Of the species of seed recommended to be so treated the authors report tests of *Agrostis*, *Aira*, *Glyceria*, *Holcus*, *Poa*, *Dactylis*, beet, and carrot seed, in which from 7.5 to 26 per cent higher germinations were secured when the higher temperature was maintained throughout the experiments.

The importance of a sufficient supply of oxygen and the proper amount of moisture in the seed bed is pointed out. The results of a number of experiments in which there was an insufficient supply of oxygen are tabulated, in which the deficiency attributed to this cause varied from 1.5 to 50 per cent. The preliminary soaking of ordinary seed before placing them in the seed bed is without ultimate effect, although seeds with hard seed coats may be benefited by a brief soaking in hot water.

The effect of light on the germination of seeds is commented upon and in the case of seed of *Poa* spp. it exerts a very beneficial effect, as is shown in the following table. All seed were germinated in thermostats at a temperature of 30° C., the comparisons being made of seed from the same lots.

*Effect of light on germination of grass seed.*

	In direct sunlight.	In diffused light.	In darkness.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
<i>Poa pratensis</i> .....	86.5	29.25	8.25
<i>Poa pratensis</i> (old seed).....	49.0	11.00	3.50
<i>Poa trivialis</i> .....	94.0	36.25	13.00
<i>Poa nemoralis</i> .....	71.0	53.50	14.25
<i>Poa nemoralis</i> (old seed).....	43.0	19.50	8.00

The authors describe in considerable detail their method for germinating grass seed, for which purpose they prefer a seed bed of filter paper. Sand seed beds are also described.

The question as to the proper duration of a test of seed is considered and numerous examples are cited in which the time usually given is shown to be too short.

In conclusion the authors have given in tabulated form the most important data regarding the germination of 22 of the more common grass seeds.

**Concerning the effect of formic aldehyde on germination, R. WINDISCH** (*Landw. Vers. Stat.*, 49 (1897), No. 3, pp. 223-226).—A report is given of experiments with wheat, barley, oats, and rye in which the seed was soaked for 24 hours in solutions of formic aldehyde varying in strength from 0.02 to 0.4 per cent, comparisons being made with seed soaked for the same time in distilled water. The seed was germinated between layers of filter paper which were kept constantly moistened, and the seedlings were counted every 24 hours. The duration of the experiments was from 12 to 16 days. It was found that the weakest solution retarded the germination of barley, wheat, and rye, but was favorable to the germination of oats. The strongest solution injured all the seed. The following table shows the average percentage of seed of each kind that germinated under the influence of the different strengths of the solution:

*Effect of formic aldehyde on germination.*

Kind of seed.	Distilled water.	Strength of solution.					
		0.02	0.04	0.08	0.12	0.20	0.40
Barley.....	96.50	95.50	97.50	89.00	47.00	0	0
Wheat.....	98.00	97.25	97.25	88.50	9.25	0	0
Oats.....	97.00	99.50	99.25	96.50	95.50	64.5	0
Rye.....	96.25	93.50	91.50	65.25	20.50	0	0

In every case there were duplicate experiments, and where the difference was more than 5 per cent the experiments were repeated.

**Germination tests in soil and in bare earthen cups, L. F. KINNEY and G. E. ADAMS** (*Rhode Island Sta. Rpt.* 1896, pp. 193-202).—The authors report upon parallel tests of 151 lots of seeds in which the germinations were made in soil and in bare porous cups, duplicate samples in every case being used. Of the total number of tests made only 17 gave a higher percentage of germination in the soil than in the cups. In many cases the germinations were exactly the same in each. As a whole the results of the soil tests averaged slightly lower than those in the germinators. The object of the experiment was to verify by means of soil germinations those made in the germinators, and in this manner arrive at a proper estimation of the value of seed so far as may be determined by its vitality. The results of the experiment are tabulated, showing the usual data of such tests.

**Report of the Hamburg seed control station, O. BURCHARD** (*Jahresber. Agr. Bot. Vers. Stat. und Samen-Prüfungsanstalt zu Hamburg*, 1898, VII, pp. 11).—A report is given of the investigations conducted at the station during the year ending June 30, 1897. The principal lines of investigation reported upon are seed testing, examination of

concentrated feeding stuffs, culture experiments with summer wheat, and an inoculation experiment with Nitragin.

The results of 661 tests of seeds to determine their purity, germinative ability, authenticity, and origin are tabulated. As shown in the previous reports, seeds of leguminous forage plants were largely in the majority of all seed tested. Except in the case of red clover seed, 64.5 per cent of the samples of which contained dodder seed, nearly all were free from that parasite. The investigations as to the origin of the clover seed showed a considerable mixture of seed from different countries.

The investigations with Nitragin were made with a mixture of crimson clover and hairy vetch on light sandy soils. Both the seed and soil methods of inoculation were employed and comparisons made with check plats. The plants were cut September 28, and the air-dried fodder from the inoculated plats exceeded that of the checks by 57 per cent, the 2 methods giving the same results. The author investigated the possibility of natural soil infection by sowing a mixture of 20 species of leguminous seed on marsh soil and examined the roots for tubercle formation. Of these the yellow clover and soy bean were without tubercles, the melilotus, esparcet, and kidney vetch contained a few, and red clover, white clover, alsike, the different lupines, serradella, peas, and beans were well inoculated.

**Analyses of grass and clover seeds,** W. CARRUTHERS (*Jour. Roy. Agr. Soc. England, 3. ser., 8 (1897), pt. IV, pp. 742-744*).—A brief statement is given of the testing of grass and clover seeds during the year. A growing improvement in the purity of seeds is very noticeable. The average purity and germination of a number of grass and clover seeds is given. Of the samples of clover seed examined 10 per cent contained dodder. Samples of alsike clover were free from dodder but frequently contained other mixtures. A brief report is made on grass mixtures, some of which are said to have been of very low grade. Several samples of hay were botanically analyzed and one is reported upon which contained altogether 13 per cent of undesirable weeds. This sample was of such a nature that cows refused to eat it unless salted or chopped and mixed with meal.

**Determination of weeds,** W. CARRUTHERS (*Jour. Roy. Agr. Soc. England, 3. ser., 8 (1897), pt. IV, pp. 738-742, figs. 5*).—Notes are given on the occurrence of the following weeds: Echanter's nightshade, mouse-ear chickweed, winter cress, bitter cress, hedge mustard, wild radish, 2 species of clover, parsley piert, wild camomile, pepper saxifrage (*Silene pratensis*), hawkweed, woolly cudweed, *Pyrethrum inodorum*, comfrey, ground ivy, saffron, *Polygonum bistorta*, and crow or wild garlic.

Notes are given on the injurious qualities of some of these plants when eaten by stock. Echanter's nightshade is reported as being poisonous, but an examination of the stomach of a cow which was

reported to have died from eating this weed revealed the presence of a great many other plants but no trace of this plant. Wild camomile and parsley piert are reported to have caused a peculiar disease of sheep, from which they recovered when placed in a field not containing these plants. Further information is desired relative to the injurious properties of these plants. The pepper saxifrage is said to have caused serious injury, since the butter made from milk of cows pasturing in a meadow where this plant was abundant was unsalable. When the plant was fed to pigs it made them sick. Its strong essential oil is probably the cause of its undesirable character. Meadow saffron and wild garlic are both considered undesirable weeds, the first on account of being an irritant poison and the second because of the strong smell and pungent taste which it gives to milk and butter from cows feeding in pastures where it occurs.

Concerning the valuation of some important agricultural seeds, D. SAKELARIO (*Wiener Illus. Gart. Ztg.*, 23 (1898), No. 2, pp. 50-66).

Seed control, J. E. JACOBSEN (*Ugeskr. Landm.*, 42 (1897), Nos. 27, pp. 344-348; 33, pp. 431-433).

Two solanums reputed to be poisonous to stock (*Agr. Gaz. New South Wales*, 9 (1898), No. 1, pp. 37, 38).—Notes are given of *Solanum escuriale* and *S. ellipticum*.

Troublesome or injurious plants, G. HEUZE (*Jour. Agr. Prat.*, 2 (1897), No. 47, pp. 779, 780).—Notes are given of *Ernea sativa*, *Raphanus raphanistrum*, *Ranunculus sativus*, *Rumex acetosella*, and *Polygonum ariculare*.

## DISEASES OF PLANTS.

Diseases of plants, W. CARRUTHERS (*Jour. Roy. Agr. Soc. England*, 3. ser., 8 (1897), pt. IV, pp. 735-738).—The author briefly discusses a number of diseases of cultivated plants and suggests the best remedies, so far as known, for their prevention. He reports having found timothy attacked by *Spumaria alba* and *Cladosporium herbarum*; and clovers by *Peronospora trifolii*, *Sclerotinia trifolium*, and *Pseudopeziza trifolii*. Among the diseases of cruciferous plants are mentioned attacks of *Plasmodiophora brassica* on various root crops and *Uromyces betæ* as having been found on leaves of mangel-wurzels. An undetermined disease of mangel-wurzels is also noted. It attacks the tuber at its base, involving both the tuber and the smaller roots, and spreading, ultimately destroys the whole plant. There are said to be associated with this disease several species of bacteria.

Several samples of peas which were suffering from attacks of different species of fungi were received. For preventive remedies the author suggests the liberal use of Bordeaux mixture. *Puccinia asparagi* on asparagus is figured and described, and it is recommended that all diseased plants should be cut to the level of the ground and burned.

Two diseases of forest trees are briefly described, caused by *Dasy-scypha willkommii* on the larch and *Rosellinia ligniaria* on the ash.

Rust and leopard spot of asparagus, W. G. JOHNSON (*Maryland Sta. Bul.* 50, pp. 163-168, pl. 1).—The author figures and briefly

describes two diseases of asparagus which have caused considerable loss to asparagus growers in his State. The asparagus rust is due to *Puccinia asparagi*. The other disease is apparently of fungus origin, although it has not been determined. Cutting and burning over infested fields in midsummer has been resorted to as a method of control, but it is questioned whether such treatment would not prove harmful to the vitality of the plants if continued for several years. Until some better method is discovered this means will perhaps be the one most frequently employed. The use of fungicides, especially when applied in large fields, the author thinks will not offer much help. The character of the soil and method of fertilizing seem to be without any particular effect in securing immunity from the disease.

**Recent investigations concerning the leaf spot disease of beets,** FRANK (*Ztschr. Ver. Rübenz. Ind., 1897, p. 589; abs. in Centbl. Bakt. u. Par., 2. Abt., 3 (1897), No. 25-26, pp. 751, 755*).—The fungus causing the characteristic gray spots on the leaves of the beet is said to be *Cercospora beticola*, and while most evident upon the leaves it is not confined to them, but invades the tissues of all the above-ground portions of the plant as well as the roots themselves. The recent investigations of the author indicate that the fungus may be carried over from one crop to another through the seed balls. Soaking them for 24 hours in a weak solution of Bordeaux mixture (2 to 4 per cent solutions), after which they are spread to dry, is recommended as a means for preventing much of the injury from attacks of this disease.

**Fairy ring disease of carnations,** L. F. KINNEY (*Rhode Island Sta. Rpt. 1896, pp. 203-206, pl. 1, fig. 1*).—An account is given of a disease of carnations which has proved of considerable injury to plants grown under glass during the past season. The Daybreak variety seems to be particularly susceptible to the disease. Attempts have been made with several fungicides to prevent its attacks, but after several weeks' trial all were abandoned except Bordeaux mixture. On account of the discoloration due to Bordeaux mixture it reduces the market value of the plants and should not be used for a considerable time before blooming. The author thinks that the use of fungicides during the summer and the planting only of strong, healthy plants in the house will gradually reduce the amount of disease.

**Carnation rust,** L. F. KINNEY (*Rhode Island Sta. Rpt. 1896, pp. 207-210, figs. 3*).—Notes are given on the occurrence of carnation rust, and the results of experiments with Bordeaux mixture are reported. The fungicide was used with decidedly beneficial results on a bed of McGowans when the plants were in bloom. The sprayed plants bloomed more freely, but there was no indication that the mixture would completely control the attack. As in the case of the treatment for fairy ring disease the application of Bordeaux mixture should be made early in the season.

Another troublesome disease of carnations is briefly reported upon. It results in the deformity known among growers as "petrified" buds.

It is thought to be due to the too extensive forcing of the plants and consequently can be very easily avoided.

**The plum rot and its effect on plum culture in Rhode Island,** L. F. KINNEY (*Rhode Island Sta. Rpt. 1896, pp. 191, 192*).—Brief notes are given on the occurrence of black knot, curculio, and the plum rot fungus. The first 2, according to the author, may be more or less successfully combated, but his conclusions relative to the treatment for the prevention of plum rot indicate that the disease can not be controlled by spraying the trees with Bordeaux mixture. It is stated that plum trees heavily sprayed with strong Bordeaux mixture were severely attacked by plum rot. The varying susceptibility of different varieties toward disease is mentioned. This seems to be due in part at least to a difference in the texture of the skin of the fruits, although early varieties are reported as more commonly injured than those which ripen their fruit later. At present it is thought that the Japanese varieties are more resistant than the European, but further discussion of them is deferred.

**The root rot of tobacco caused by *Thielavia basicola*,** V. PEG-LION (*Centbl. Bakt. u. Par., 2. Abt., 3 (1897), No. 21-22, pp. 580-583*).—This disease, which consists of the rotting away of all secondary roots from the main root of the plants, is said to attack some varieties of tobacco more severely than others, Kentucky Burley and to a less extent Seed Leaf being especially susceptible. The rotting away of the secondary rootlets is soon followed by the rapid yellowing of the plant. Adventive roots are put out and the plants sustained for a time, but usually all diseased subjects dry up and perish.

Microscopic examination showed the presence of *Thielavia basicola*, a fungus already known to attack the roots of various cultivated plants, among them *Lupinus luteus*, *L. angustifolius*, *L. albus*, *Trigonella carulea*, *Onobrychis crista-galli*, *Pisum sativum*, etc. The relationships of the fungus and its description are given in considerable detail.

Until more is known concerning rational methods of soil disinfection and relative resistance of different varieties, those varieties known to be least liable to disease should be planted.

**The periods favorable for treatment against black rot,** A. PRUNET (*Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 22, pp. 889-891*).—The author gives a brief account of experiments made to determine the proper time for spraying grapevines to secure immunity from attacks of the black rot fungus.

In the region where the experiments were conducted it was found that the first important appearance of the disease was noted on May 18. Those vines which had received a single spraying about April 20, when the young shoots are 15 to 20 cm. long, were almost wholly free from disease. Single sprayings made April 12 or 13 were less efficient, and after April 29 were of little effect. Two sprayings, April 20 and May 12, were about equal to the single application at the first date,

while spraying on April 28, May 5, 12, and 17 were of no more effect than a single one in preventing attacks of the fungus.

For the later attacks of the disease the author states that a single spraying is sufficient. For the maximum results the application should be made from 2 to 5 days after the most acute period of invasion by the fungus or 5 to 8 days after the appearance of the first spots on the leaves.

As an explanation the author states that at about the dates indicated the young organs of the plant are in a most receptive condition and the spores are at that time being widely disseminated so that the copper solution finds the best conditions for its efficiency.

**Studies on root rot and other injuries to ligneous plants**, F. CAVARA (*Staz. Sper. Agr. Ital.*, 29 (1896), pp. 788-814; *abs. in Ztschr. Pflanzenkrank.*, 7 (1897), No. 6, pp. 360, 361).—Notes are given of the injury to trees through attacks of *Calococca viscosa*, *Tremellodon gelatinosum*, *Polyporus versicolor*, *P. sulphureus*, *P. cuscus*, *P. abietinus*, *Tricholoma saponaceum*, *Myceena epipterygia*, *Pleurotus viduans*, *Hygrophorus pudorinus*, *Flammula penetrans*, *F. spumosa*, *Pholiota aurivella*, and *Lycoperdon gemmatum*.

**Culture experiments with heterocœcious rust fungi**, H. KLEBAHN (*Ztschr. Pflanzenkrank.*, 7 (1897), No. 6, pp. 325-345, figs. 4).—Studies are given of *Melampsora* spp., *Peridermium strobil*, and *P. pini*.

**The hexenbesens of cherry trees and their prevention**, K. VON TUBEUF (*Prat. Bl. Pflanzenschutz*, 1 (1898), No. 1, pp. 4-6, figs. 2).

**Two destructive celery blights**, B. M. DUGGAR (*New York Cornell Sta. Rpt.* 1897, pp. 201-220, figs. 13).—A reprint from Bulletin 132 of the station (E. S. R., 9, p. 358).

**A disease of currant canes**, E. J. DURAND (*New York Cornell Sta. Rpt.* 1897, pp. 22-38, figs. 13).—A reprint of Bulletin 125 of the station (E. S. R., 9, p. 359).

**A disease of chestnut trees**, E. ROZE (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 23, pp. 982, 983).—The chestnut is said to be exceptionally subject to attacks of *Pseudococcis ritis*, the cysts or plasmodia of which readily gain entrance through the leaves and young branches. The fruit through its spiny envelope also offers a good medium for attacks of the organism and the attack on the fruit is often associated with *Aspergillus glaucus*.

**A new disease of firs**, F. CAVARA (*Ztschr. Pflanzenkrank.*, 7 (1897), No. 6, pp. 321-325, pl. 1).—Notes are given of attacks of *Encarbitaria pithyophila cembra* on *Abies pectinata*. From the nature of the disease the affected portions should be cut away and burned.

**On the development of the white rot of grapes (*Charrinia diplodiella*)**, P. VIALA (*Ann. Ecole Nat. Agr. Montpellier*, 9 (1895-'96), pp. 266-268).

**The lily disease**, B. D. HALSTED (*Amer. Florist*, 13 (1898), No. 510, p. 882, fig. 1).—Briefly describes the Bermuda lily disease, quoting from U. S. Dept. Agr., Division of Vegetable Physiology and Pathology Bulletin 14 (E. S. R., 9, p. 658).

**Diseases of the potato**, E. G. LODEMAN (*New York Cornell Sta. Rpt.* 1896, pp. 295-331, pl. 1, figs. 2).—A reprint of Bulletin 113 of the station (E. S. R., 8, p. 137).

**Rust experiments**, F. MADDOX (*Agr. Expts. Eastfield, Tasmania*, 1897, pp. 85-90).—The author gives a review of experiments conducted with different rusts in which various facts relative to the life history of the fungus were investigated, and he concludes that their life history is by no means understood.

**Latest experiences concerning rust on small grains**, E. ROSTRUP (*Ugeskr. Landm.*, 43 (1897), No. 48, pp. 637-639).

**What is grain rust and how can it be checked?** J. ERIKSSON (*Hvad är Sädessrost och hvad kan göras mot densamma?* Stockholm: P. A. Norstedt & Söner, 1896, pp. 82).

**Does it pay to spray?** (*Ontario Dept. Agr. Special Bul., 1897, Dec., pp. 8*).—A report is given of the results obtained in spraying 29 orchards in different parts of the Province of Ontario in which the benefits derived from the application of Bordeaux mixture in reducing the amount of apple scab and other diseases was plainly shown. Brief letters are given from the owners of the different orchards in which are stated their opinions relative to the success and the value of the treatment.

**Spray calendar**, E. G. LODEMAN (*New York Cornell Sta. Rpt. 1896, pp. 335-343, figs. 4*).—A reprint of Bulletin 111 of the station (E. S. R., 8, p. 149).

**The effect of spraying Bordeaux mixture on foliage**, F. C. HARRISON (*Canad. Hort., 21 (1898), No. 3, pp. 99-101*).

**Experiments for the prevention of Botrytis cinerea on grapes**, J. BURNAT (*Prog. Agr. et Vit., 28 (1897), No. 47, pp. 551-593*).—Reports successful experiments with a powder composed of cement, steatite, and hydraulic lime, in the proportion of 2, 3, and 5 parts.

**Experiments with fungicides for the prevention of grape anthracnose**, G. GOURAND and G. BERGERON (*Rev. Vit., 7 (1897), No. 159, p. 5; abs. in Centbl. Bakt. u. Par., 2. Abt., 3 (1897), No. 21-22, pp. 603, 604*).—Experiments were conducted with solutions of copper sulphate, iron sulphate, and sulphuric acid for the prevention of grape anthracnose due to *Sphaceloma ampelinum*. Ten per cent solutions of sulphuric acid gave good results when applied to the vines early in the spring. Similar results were secured with the iron sulphate. The use of copper sulphate was not so successful.

**Results of experiments in 1896 to combat grape mildew**, G. CUBONI (*Bol. Not. Agr., 19 (1897), pp. 401-411; abs. in Ztschr. Pflanzenkrank., 7 (1897), No. 6, pp. 355, 356*).—A number of fungicides were tested for the prevention of grape Peronospora, comparisons being made with Bordeaux mixture.

Copper acetate was found inferior to Bordeaux mixture. A copper-soda mixture, while about as efficient as Bordeaux mixture, was more expensive. Copper sulphate, boral, and Statnti's mixture proved worthless.

**A new grape parasite**, L. MONTEMARTINI (*Atti. Istit. Bot. Univ. Paria, 1897; abs. in Ztschr. Pflanzenkrank., 7 (1897), No. 6, pp. 359, 360*).—Under the name *Aureobasidium vitis album* the author describes a new variety of this micromycete, which is parasitic on the grapevine.

## ENTOMOLOGY.

**Brood XV of Cicada septendecem in Ohio**, F. M. WEBSTER (*Canad. Ent., 29 (1897), No. 10, pp. 225-229, figs. 3*).—In this paper, which was read before Section F of the American Association for the Advancement of Science at its Detroit meeting, August 10, 1897, the author gives an account of his study of Brood XV of the 17-year locust. It was found to occupy the whole of the eastern half of the State of Ohio with the exception of a strip along the lake region and the northeastern counties of Ashtabula and Trumbull, and the eastern portion of Mahoning and Columbiana and most of Lawrence and Galla counties in the southern part of the State. The brood appeared to be less in numbers than formerly, and it is thought to be on the decline, so that in time it will be known only in history. The later appearing members of the brood were attacked severely by a tachina fly, but the greatest enemies of the locusts seem to be various birds, such as the English sparrow, crow blackbird, and robin. The first of these seemed to be exceedingly fond of them, since they paid no attention to *Pieris rapae* and some other butterflies of the neighborhood.

**A report of the entomological department, A. D. HOPKINS** (*West Virginia Sta. Rpt. 1896, pp. 66-164, figs. 2, pls. 4, maps 3*).—In the first part the author reviews his work from 1890 to 1896, describes his various collections, and gives a bibliography of his original researches. Forest entomology was dealt with especially. The importation of the European bark beetle destroyer (*Clerus formicarius*) is noted as successful. The defects in wood produced by insects were studied. The destructive heartwood borer (*Centrodera decolorata*), along with the chestnut timber worm (*Corthylus columbianus*), was found in living trees where fires and other agencies had broken the bark sufficiently to expose the wood. The latter of these 2 insects was found in oak, tulip, and other kinds of wood, in which it produced what are known as black hole stains, ribbon or calico wood. A parasite (*Aphidius lactuca*) was experimented with in the greenhouse, where it kept its host (*Aphis brassicae*) so subdued that no other remedies were needed. The remainder of this part deals with incidental matter.

*The principal insect depredations and depredators noted in the State during the past 5 years* (pp. 93-110).—In this second part the author reports briefly the results of studies of dying pine, spruce, yellow locust, hemlock, and oak; the defoliation of forest trees, shade, and fruit trees; tan bark destroyed by insects (*Phymatodes variabilis*); wormy chestnuts and hickory nuts; the bag worm (*Thyridopterix ephemeraformis*); the elm leaf beetle (*Galerucella luteola*); and the common farm and garden insects and fruit insects. Among the last the imported fruit bark beetle (*Scolytus rugulosus*) is noted. The San José scale is mentioned as reported from 2 counties.

The remainder of this part deals briefly with the common insects affecting live stock and the common household insects.

*A study of agricultural conditions in West Virginia and the needs of entomological work* (pp. 111-164).—Here are discussed in a very general way geographical, geological, and climatic conditions, life zones, forest areas of the State, designated as spruce, pine, and hard-wood areas, and the relation of forest divisions to life zones.

Finally there is a paper on some discoveries and observations made during 1894 and 1895, in which the borer *Agrilus bilineatus*, the habits of *Corthylus punctatissimus*, and *Agrilus* sp., the elm and pine borer (*Gortyna nitela*, *Cyllene picta*, *Corthylus columbianus*), and a number of other more or less common insects are noted. *Cyllene picta*, it is shown, emerges in the fall. Woodpeckers are mentioned as causing considerable loss of timber. *Epidapus scabicus* (= *E. scabici*) is noted as attacking potato tubers, causing potato scab. It is said that the presence of stable manure and moisture is a very important factor favoring the development of the insects.

This and the remaining papers—some observations on the gall mite, some notes on insect enemies of trees, and on farm, garden, and fruit insects—are reprints of articles that have appeared elsewhere.

**The immature stages of *Diabrotica soror***, R. W. DOANE (*Jour. Ent. Soc.*, 5 (1897), No. 1, pp. 15-17).—The hitherto unknown history of this insect has been studied.

The oval, dirty white egg measures 0.7 by 0.5 mm. and has a finely sculptured surface, due to the hexagonal areas formed by the follicular cells. The full-grown larva measures 12 mm. in length and tapers slightly toward the head. The general color is white, often turning yellowish near the time of pupation. The head, dorsal shield, and the last abdominal segment are brown. There is but a single pair of fleshy prolegs. Near the posterior end are several strong marginal hairs and 2 subtriangular processes.

The pupa is whitish or straw-colored and measures 4 by 2 mm. and is provided with brown hairs more or less definitely arranged. The eggs are deposited from  $\frac{1}{4}$  to  $\frac{1}{2}$  in. below the surface of the ground near the base of some plant. Usually from 20 to 50 are laid in one spot, but sometimes only one. The larvæ develop slowly, for they were found in various sizes on the roots of plants in March, April, and May. The roots are eaten on the outside and are not bored into. The range of food plants is wide. Larvæ are often found in abundance on roots of sweet peas and alfalfa. The adults often give fruit growers considerable trouble by eating young fruit.

**The number of molts in insects of different orders**, A. S. PACKARD (*Psyche*, 1897, No. 258, pp. 124-126).—The number of molts varies with the latitude, temperature, and other conditions. Semi-starvation and consequent prolongation of life seems to favor an increase in the number. Some species molt once more in the southern than in the northern United States. In Campodia there is a single fragmentary molt, according to Grassi, and in Collembola (*Macrotoma plumbea*), according to Sommer, the skin is shed throughout life. Hibernating larvæ molt oftener than summer broods. Among Orthoptera the number of molts varies from 2 (*Diapheromera femorata*) to 7 (*Mantes religiosa* and *Periplaneta americana*). Among Homoptera there are from 2 to 4 molts. In the May fly (Chelou) there are 20 molts. In the neuroppterous *Ascalaphus insimulans* of Ceylon there are 3. Plecoptera (Pantopora) molt 7 times; in Coleoptera the number varies so far as known from 3 (*Phytonomus punctatus*) to more than 15 (*Trogoderma tarsale*). Siphonaptera molt 3 times. In Lepidoptera the average number of molts is 4, the greatest number known being 11 (*Phyoraetia isabella*). Among the Diptera there are from 2 (Calliphora) to 11 (*Harpiphorus varianus*). In the Hymenoptera (*Aphis mellifica*) there are, according to Chesshire, probably 6 molts.

**Monograph of the genus *Aspidiotus***, G. LEONARDI (*Riv. Pat. Veg.*, 5 (1896-97), No. 9-12, pp. 283-286).—In this, a preliminary note, Leonardi proposes the new genera of the Aspidioti, Odonaspis, Chen-traspis, and Phanlaspis and arranges the numerous species of the 9 genera of the group as follows: A. *Aspidiotus nerii*, *juglans-regie*, *pini*,

*spinus*, *patirinus*, *abietis*, and *thea*; B. *Aspidiotus sacchari*, *hartii*, *zonatus*, *maculatus*; C. *Aspidiotus ancylus*, *ura*, *eydonia*; D. *Aspidiotus articulatus*; *Aonidia lauri* and *cornigera*; *Aspidites camellia* and *minimum*; *Chrysomphalus ficus*, *spherioides*, *magnifera*, *nigropunctatus*, *dictiosperma*, *obscurus*, *persea*, *rossi*, *minor*, and *degeneratus*; *Targionia nigra*, *vitis*, and *prospoidis*; *Aonidiclla aurantii*, *fusca*, *perniciosa*, *tenebricosa*, *mimosa*, *personata*, and *smilacis*; *Odonaspis secreta*; *Chentraspis extensa* and *milobis*; and *Phaulaspis hakea*.

**The army worm in Rhode Island**, C. O. FLAGG AND G. W. FIELD (*Rhode Island Sta. Rpt. 1896*, pp. 319-326, fig. 1).—Twenty-eight replies received in response to a circular showed that the army worm was present and doing more or less damage in 5 counties. The crops reported damaged were oats in 9 cases, barley 5, Hungarian grass 4, corn 3, and grass 2. Hungarian grass sown late was reported as entirely destroyed. A brief account of the life history of the insect is given and the following destructive agencies noted: Robin, bluebird, blackbird, bobolink, meadow lark, pigeon woodpecker (*Colaptes auratus*), a black predaceous ground beetle, Tachina and Ichneumon flies, spiders' webs, electric lights, and a large ground spider (*Epeira*) that feeds on caterpillars. It is also noted that the insects seemed to be attacked by an infectious disease that carried them off in great numbers. To these natural checks the rapid disappearance of the pest is attributed.

The preventive measure noted is the ordinary one of furrowing and the use of lines of tar.

**The army worm in New York**, M. V. SLINGERLAND (*New York Cornell Sta. Rpt. 1897*, pp. 233-258, pls. 2, figs. 3).—A reprint of Bulletin 133 of the station (E. S. R., 9, p. 365).

**Some of the injurious insects of Pennsylvania**, C. W. JOHNSON (*Pennsylvania Dept. Agr. Rpt. 1896*, pp. 345-373, pls. 2).—The paper notes the San José scale (*Aspidiotus perniciosus*), the cotton maple scale (*Pulvinaria innumerabilis*), the rose scale (*Diaspis rosea*), the bag or basket worm (*Thyridopteryx ephemeraformis*), the white marked tussock moth (*Notolophus* [*Orygia*] *leucostigma*), the oak carpenter worm or borer (*Prionoxystus robinia*), locust borer (*Cyrtene robinia*), the broad necked prionus (*Prionus laticollis*), stag beetles (*Lucanus dama*), May beetles (*Lachnosterna* spp.), rose beetle (*Macrodaetylus subspinus*), asparagus beetle (*Crioceris asparagi*), the new asparagus beetle (*Crioceris 12-punctata*), the fruit bark beetle (*Scolytus rugulosus*), the hickory bark borer (*Scolytus 4-spinosus*), the pine bark beetle (*Tomicus cacographus*), the potato stalk borer (*Trichobaris trinotata*), the thick thighed walking stick (*Diapheromera femorata*), as well as the remedies against each.

A chapter is given on the subject of sparing the insectivorous birds, and on imprisoning and fining the snarer.

**Contributions from the New Mexico Biological Station No. 2 on a collection of Diptera from the lowlands of the Rio Nantla in the State of Vera Cruz**, II, C. H. T. TOWNSEND (*Ann. Mag. Nat. His.*, 6. ser., 20 (1897), 117, pp. 172-221).—This paper takes up the Trichopoda, some 22 species and varieties of which are tabularly distinguished, and the new varieties, *T. histrio indivisa* and *T. lanipes tropicalis* and the new species *T. phasiana* described. The last is distinguished by its wings, being black only on the costal third, and by its black abdomen with two basal yellow spots.

Pennapoda is described as a new subgenus which is distinguished by the abdomen being nearly of the same shape in both sexes, rounded at the tip and narrowed slightly at the base. It is connected with Trichopoda proper by the forms of *T. histrio*.

A new variety of *Lipoptena depressa* of the Hippoboscidae, namely, *L. mexicana*, is also described. *L. depressa* breeds at times and probably always on deer, and the author thinks it is always wingless.

On the systematic position of the hemipterous genus *Phimophorus*, A. HANDLIRSCH (*Verhandl. K. K. Zool. Bot. Gesell. Wien*, 47 (1897), No. 8, pp. 558-560, figs. 2).

The larva of *Crocota opella*, H. G. DYAR (*Psyche*, 8 (1897), No. 257, p. 119).—The egg, the three larval stages, and the cocoon are described. The eggs are laid at the end of July and the half-grown larvæ hibernate during the next winter. The eggs are deposited in patches on the leaves of bushes and trees, but the larvæ drop to the ground on hatching. Almost any tender leaves are eaten.

Bramble stalks and their inhabitants, RUDOW (*Illus. Wehnschr. Ent.*, 2 (1897), Nos. 14, pp. 209-213, figs. 20; 15, pp. 235-238).—The habits of *Diastrophus rubi*, *Torymus macropterus*, *Proctotrupes*, *Synopcas*, *Lasioptera rubi*, *Diastrophus turgidus*, *D. nebulosus*, *D. cuscutiformis*, *Cecidomyia conifera*, *C. cornifer*, *C. tumifica*, etc., are described.

On *Plusia moneta*, PABST (*Illus. Ztschr. Ent.*, 2 (1897), No. 44, pp. 695-697).—Observations on the food plants and the life history. The species occurs on several species of *Aconitum* and *Delphinium*. On the first the young larvæ attack first the terminal leaves, while on *Delphinium* they attack the leaves anywhere.

*Bombyx neustria*, C. SCHROEDER (*Illus. Ztschr. Ent.*, 2 (1897), No. 43, pp. 673-678, figs. 4).—The ravages of this moth on *Prunus spinosa* and *Pyrus malus* are figured and the habits of the insect and its food plants discussed.

Aphidological contributions, N. CHOLODKOVSKY (*Zool. Anz.*, 1896, No. 520, pp. 508-513; rev. in *Zool. Centbl.*, 4 (1897), No. 26, pp. 918, 919).—The elm leaf louse (*Schizoneura ulmi*) is thought to have but one gall generation. *Colopha compressa* of Koch is regarded as identical with the American *Colopha ulmicola*. The intermediate generation of *C. compressa* was found on the roots of *Aira cuspitosa*. Other aphids noted are *Lachnus hyalinus*, *L. picicola*, *L. pincus*, *L. taniatus*, *L. bogdanowi*, *L. juniperi*, *L. nudus*, *L. farinosus*, *L. piueti*, *L. agilis*, *Schizoneura fodicus*, and *Chermes abietis*.

On some *Phasmia* forms, E. GIRSCHNER (*Illus. Wehnschr. Ent.*, 2 (1897), No. 3, pp. 33-36, figs. 7).—*Phasmia magnifica*, n. sp., is described.

Two notable aberrations in *Vanessa antiopa* and a new method of producing aberrations by cold, E. FISCHER (*Illus. Wehnschr. Ent.*, 2 (1897), No. 11, pp. 161-167).—Cold was obtained with sulphuric ether and the pupæ were subjected to -2° C. for 5 minutes and then removed to the temperature of the room, 20° C. Out of 24 pupæ 15 abnormal forms were obtained.

*Mamestra pisi*, C. SCHROEDER (*Illus. Wehnschr. Ent.*, 2 (1897), No. 12, pp. 177, 178, pl. 1).—The larvæ of this moth is shown to very closely resemble *Helix nemoralis* when it is coiled up.

The influence of water on the life of larvæ, H. GAUCKLER (*Illus. Wehnschr. Ent.*, 2 (1897), No. 19, pp. 295, 296).—The author concludes that those larvæ that seek sunlight may be injured by dampness and those that live in moist situations may be injured by light, etc.

Notes on the transformations of higher Hymenoptera, III, A. S. PACKARD (*Jour. New York Ent. Soc.*, 5 (1897), No. 3, pp. 109-120, figs. 5).—Descriptions of the larvæ and pupæ of *Aphis mellifica*, *Bombus separatus*, *B. vagans*, *Anthrax sinuosa*, *Xylocopa virginica*, *Ceratina dupla*, and *Megachile centuncularis*.

The compound eyes of Ephemeriidæ, C. ZIMMER (*Ztschr. Wiss. Zool.*, 63 (1897), No. 2, pp. 236-262, pls. 2).—After a minute study of the eyes of *Cloë fuscata* and other Ephemeriids the author concludes that such divided eyes as are found in this form are not uncommon among insects and that their function seems to be the same. This division of the eye into two more or less distinct parts is found where the conditions of life render it necessary to recognize motion, especially the motion of the female.

The glandular hairs of the larva of the Nonne, J. INGENITZKY (*Horæ Soc. Ent. Ross.* [St. Petersburg], 30 (1896), pp. 130-136, pl. 1; abs. in *Zool. Centbl.*, 4 (1897), No. 25, pp. 874, 875).—The author studied the hairs and cells beneath them in *Ocneria dispar*, *O. monacha*, and *Cæthocampa processionæ*. The bladder hairs (aërophore), discovered by Wachtl and Kornauth in the young larvæ, the author finds to be lost

at the first molt and succeeded by ordinary hairs. Beneath the hairs he finds two kinds of hypodermis cells, one with branching nuclei and forming monocellular glands, and a cell without a branching nucleus that becomes greatly developed during molting, and further small cells that form the chitinous collars of the hairs. The trichogen cells described by A. S. Packard the author considers glandular cells and the poison cells as hypodermal cells and collar cells.

Some remarks on the developmental states of the leaf wasps, RUDOW (*Illus. Wchuschr. Ent.*, 2 (1897), No. 17, pp. 263-266, figs. 14).—The galls produced by *Trichosoma sorbi*, *Abia fasciata*, *A. sericea*, etc., are described.

Descriptions of new cynipidous galls and gall wasps in the United States National Museum, W. H. ASHMEAD (*Proc. U. S. Nat. Mus.*, 19 (1897), pp. 113-136).—A new genus, *Compsodryoxenus*, and 43 new species are described.

*Dichelomyia* galls, C. SCHROEDER (*Illus. Wchuschr. Ent.*, 2 (1897), No. 22, pp. 339-345, figs. 6).—The form of the galls and the leaf deformations produced by flies of this group are described and figured.

Some notable gall formations, RUDOW (*Illus. Ztschr. Ent.*, 2 (1897), No. 41, pp. 645-649).—The formation and the form of galls produced by plant lice on *Populus* and some other trees are described.

Three interesting Staphylinidæ from Queen Charlotte Islands, J. H. KEEN (*Canad. Ent.*, 29 (1897), No. 12, pp. 285-287, figs. 3).—*Liparocephalus brevipennis* and *Tanyrhinus singularis* are discussed.

The life history of *Epeiranthis obfirmaria*, T. W. FILES (*Canad. Ent.*, 29 (1897), No. 11, pp. 258, 259).—The adult, eggs, and larva are described. The larvæ fed on *Vaccinium*, *Cassandra*, etc.

Notes on the life history of *Colias interior*, H. H. LYMAN (*Canad. Ent.*, 29 (1897), No. 11, pp. 249-258).—The egg, the larva in its various stages, the chrysalis, the pupa, and the adults are described.

Notes on *Grapta interrogationis*, H. H. LYMAN and A. A. WINN (*Canad. Ent.*, 29 (1897), No. 12, pp. 273-277).—This is a collection of miscellaneous notes on the life history, etc., of this insect. It is thought that the third brood must certainly hibernate.

A new food plant for *Papilio asterias*, G. H. FRENCH (*Canad. Ent.*, 29 (1897), No. 11, pp. 263, 264).—*Ruta graveolens* and *Faniculum officinale*.

The agrarian Acari, A. BERLESE (*Riv. Patol. Veg.*, 6, No. 1-5, pp. 1-66, figs. 40, pls. 4).—This is a portion of a monograph on the subject. This part of it is occupied with a description of the anatomical features, the terminology, and the habits of the agrarian mites, and the influence of surrounding conditions upon them. Considerable space is also given to a discussion of their means of offense and defense. The means of defense the author classes as epidermal projections of the integument, citing as example *Leiosoma palmicinetinum* and *Tegeocerans cepheiformis*; peculiar secretions, such as are found in the Tyroglyphidæ; peculiar capsules constructed by the mites, and protective coloration.

Life history of *Pyromorpha dimediata*, H. G. DYAR (*Psyche*, No. 258, Apr., pp. 128, 129).—The peculiar habit of the larvæ of this insect has hitherto prevented its detection, but the author has found it below fallen leaves in oak woods. The period from egg to pupa state is stated to be 3 months, or from June 15 to September 15. The pupal stage passes the winter. The colorization is dark, so as to harmonize with the surroundings. The egg and 6 larval stages and the pupæ are described somewhat in detail.

New species of *Chionaspis*, R. A. COOLEY (*Canad. Ent.*, 29 (1897), No. 12, pp. 278-282).—*Chionaspis cockerelli* taken from palm imported from China to San Francisco, *C. aucubæ* imported on aucuba from Japan, *C. wistarivæ* found on bark of wistaria from Japan, *C. pinifoliæ heterophyllæ* found on Cuban palm (*Pinus heterophyllæ*) from Florida, and *C. latissima* taken from the under side of the leaves of *Distylium racemosum* from Japan.

On the generic position of some bees hitherto referred to *Panurgus* and *Callopsis*, T. D. A. COCKERELL (*Canad. Ent.*, 29 (1897), No. 12, pp. 287-290).—The new genus *Pseudopanurgus* and the new species *Halictoides campanula* are described. The distinctive features of the several genera discussed are briefly brought out in tabular form.

A complete course in apiculture, G. DE LAYENS and G. BONNIER (*Cours complet d'apiculture*. Paris: Paul Dupont, n. d., pp. 439, figs. 243).—This is a treatise briefly covering nearly all the questions to which the amateur apiculturist may desire an answer.

How to render small amounts of wax, E. I. ABBOTT (*Amer. Bee Jour.*, 37 (1897), 36, pp. 564, 565).

Economic entomology, J. H. PANTON (*Ontario Dept. Agr. Rpt. 1896*, pp. 168-200, figs. 86).—Report of the superintendent of Farmers' Institutes of the Province of Ontario, 1896-97. This gives the estimate of the damages done by injurious insects in several of the States and in Canada for the years 1854-84, and forms a brief popular treatise on the subject of economic entomology.

The pear psylla and the New York plum scale, M. V. SLINGERLAND (*New York Cornell Sta. Rpt. 1896*, pp. 105-122).—A reprint of Bulletin 108 of the station (E. S. R., 8, p. 142).

Wireworms and the bud moth, M. V. SLINGERLAND (*New York Cornell Sta. Rpt. 1896*, pp. 71-101, figs. 24).—A reprint of Bulletin 107 of the station (E. S. R., 8, p. 143).

The currant stem girdler and the raspberry cane maggot, M. V. SLINGERLAND (*New York Cornell Sta. Rpt. 1897*, pp. 41-60, pls. 3, figs. 5).—A reprint of Bulletin 126 of the station (E. S. R., 9, p. 363).

Green fruit worms, M. V. SLINGERLAND (*New York Cornell Sta. Rpt. 1896*, pp. 569-583, pls. 4).—A reprint of Bulletin 123 of the station (E. S. R., 8, p. 802).

The San José scale in Pennsylvania, G. G. GROFF (*Pennsylvania Dept. Agr. Rpt. 1896*, pp. 514-531, pls. 2).—This is mostly a popular compilation from different sources and contains a synopsis of the State laws against the San José scale.

The pistol case bearer in western New York, M. V. SLINGERLAND (*New York Cornell Sta. Rpt. 1897*, pp. 17, pls. 2, fig. 1).—A reprint of Bulletin 124 of the station (E. S. R., 9, p. 367).

Bee paralysis carried by the queen, E. GALLUP (*Amer. Bee Jour.*, 37 (1897), No. 31, p. 481).—It is stated that bees from a purchased queen were found dead in large numbers in front of their hive and that a young queen from the same mother was seen to die in an observation hive. The disease would thus appear to be hereditary. It was gotten rid of by introducing healthy queens from healthy colonies.

Propagation of the maladies of the silkworm by birds, F. LAMBERT (*Rev. Vit.*, 1897, No. 168, pp. 269, 270; *abs. in Centbl. Bakt. u. Par.*, 1. Abt., 21 (1897), No. 22-23, p. 395).

A new type of organism parasitic on Gregorines, M. CAULLERY and F. MESNIL (*Compt. Rend. Acad. Sci. Paris*, 125 (1887), No. 20, pp. 787-790, figs. 10).—There is here described under the new generic and specific name of *Metchnikovella spionis* a peculiar organism probably of parasitic nature found in the *Gregorina spionis* of the alimentary canal of the annelid *Spio martinicusis*. The organisms appear as nucleated rounded bodies. They multiply by fission and by gemmation and exist in the body of the gregorin in the form of chains or singly in elongated vacuoles. The bodies measure about  $2\frac{1}{2} \mu$  in size and are usually arranged in 2 rows of about 16 each. In the gregorine (*G. anchorina*) of the capitellid, *Capitellides giardi*, a similar organism is found. Similar bodies have been described and figured from the gregorines of other worms, but hitherto they have not been explained.

## FOODS—ANIMAL PRODUCTION.

A study of alfalfa and some other hays, W. P. HEADDEN (*Colorado Sta. Bul. 39, pp. 31*).—In continuation of previous work (E. S. R., 8, p. 768) the author reports analyses of a number of samples of alfalfa hay of the first, second, and third cuttings. In each case samples were taken of plants coming in bloom, in half bloom, and full bloom. The average results of the analyses were as follows:

*Composition of alfalfa.*<sup>1</sup>

	Water.	Protein.	Fat.	Nitrogen-free extract.	Fiber.	Ash.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
First cutting .....	7.17	15.12	1.24	30.98	34.73	10.76
Second cutting .....	7.49	17.08	1.66	36.17	26.28	11.32
Third cutting .....	8.14	15.88	1.69	34.62	28.34	11.32

<sup>1</sup> Air-dried hay.

The results of analyses made in different years at the Colorado and Utah stations are compared.

To learn whether there was any foundation for the popular belief that hay which has been stored for from 1 to 9 months in a mow or stack is preferable to older hay, a number of air-dried samples of alfalfa hay were kept for 1 to 2 years in glass stoppered bottles sealed with paraffin. The bottles were kept in the dark. In nearly every case it was found that at the end of the time the moisture and nitrogen content of the different samples had increased, though in no case was the increase regular.

"Our experiments indicate that there is no loss of the protein, but that chemical changes take place to a considerable extent in some of the other constituents, probably in those complex and less stable compounds grouped under the head of nitrogen-free extract and frequently spoken of as carbohydrates. The apparent increase of nitrogen is easily accounted for by the elimination of water and probably of other compounds also, as oxids or hydrids of carbon."

Artificial digestion experiments are reported with alfalfa hay of different cuttings kept for different lengths of time.

The coefficients of digestibility of the protein of different cuttings were as follows:

"For 1894, first cutting, 79.43; second cutting, 80.62; third cutting, 82.69; for 1895, first cutting, 80.64; for 1896, first cutting, 80.11; second cutting, 78.81; third cutting, 78.85. The average for all the cuttings made in the three years is 79.79, which is in excellent agreement with the results obtained by animal digestion.

"The results taken by years are as follows: For 1894, hay two years old, 80.91; for 1895, hay one year old, 80.64; for 1896, new hay, 79.27, from which it is clearly apparent that the proteids have not lost any of their digestibility, and from this standpoint hay which is one, or even two years old, is quite as good as new hay."

The amount of pentosans, expressed in terms of xylan, was determined in a number of samples of alfalfa hay. The results were not entirely concordant. They indicate, in the author's opinion, that—

“There are several complexes present which yield furfural, and offer different degrees of resistance to the alternate action of acids and alkalies. The complexes yielding more readily to the action of these agents predominate in the leaves, forming nearly nine-tenths of the whole amount, whereas in the stems they form only about one-half.”

Proximate analyses are reported of hay from *Stipa viridula* var. *robusta*, hay from pea vines cut in full bloom and full pod, and upland hay. The composition of the hay from *Stipa viridula* was as follows: Water 5.53 per cent, protein 8.91, fat 1.96, nitrogen-free extract 38.24, fiber 39.60, and ash 5.76. Although ordinary analysis would indicate that this hay possesses a high feeding value as compared with other hay, it is known to be of little value, since cattle will eat it only when compelled by hunger.

In order to learn something more definite of the real value of hay of different sorts analyses more detailed than those ordinarily reported were made of alfalfa hay, clover hay, pea-vine hay, and upland hay. The composition of these hays is shown in the following table:

Composition of different kinds of hay.

	Alfalfa hay coming in bloom.	Clover-hay heads, half turned.	Pea-vine hay in full bloom.	Pea-vine hay in full pod.	Upland hay.

The author sums up his work with hay as follows:

“(1) The composition of alfalfa hay grown under the same climatic conditions does not vary from year to year more than samples of the same year, which is within fairly narrow limits.

“(2) Climatic or seasonal differences do affect the composition of the hay. This, however, affects the different cuttings of the same year rather than the crops for a whole year, but this effect is comparatively small and expresses itself most pronouncedly in the percentage of crude fiber.

“(3) The amount of the protein in alfalfa hay does not decrease with but rather increases with age, if the hay is kept in a close mow.

“(4) The changes in the hay probably affect the amount and character of the nitrogen-free extract.

“(5) The protein of the different cuttings is about equally digestible, as determined by means of pepsin-hydrochloric acid. There is, however, a slight difference in favor of the hay cut when the plants were in full bloom.

“(6) The digestibility of the protein does not vary materially from year to year, nor is it affected by the age of the hay if well kept.

“(7) The lignocelluloses in alfalfa increase with the age of the plant, but there are exceptions which can not be justly attributed to methods of determination.

“(8) The presence and amount of sugar, starch, etc., depend upon the development of the plant at the time of cutting, and is at all times comparatively small.

“(9) The lignocelluloses are more abundant in the leguminous hays than in those made from our native grasses, but the cellulose is much more abundant in the latter.

“(10) The soluble portion of leguminous hay is greater than that of the little hay made from the grasses, which accounts for their susceptibility to weathering.”

**Feeding tests with barley,** W. W. COOKE (*Colorado Sta. Bul. 10, pp. 15-10*).—Experiments are reported with pigs, steers, and sheep to compare barley with wheat and corn, barley fed alone and with corn, and bald barley with common barley and with corn; and to learn the value of grinding common and bald barley. The feeding stuffs used in

the experiments were analyzed. The composition of bald barley and common barley was as follows:

*Composition of barley.*

	Water.	Protein.	Fat.	Nitrogen-free extract.	Fiber.	Ash.
	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
Common barley.....	10.09	8.66	2.47	73.82	3.09	1.87
Bald barley.....	9.44	13.21	2.69	68.55	2.77	3.34

The author quotes the digestibility of the different feeding stuffs, and assumes that bald barley would have the same digestibility as wheat.

*Experiments with pigs* (pp. 18-28).—In 1894 a test was made with 2 lots of 6 and 5 pigs, respectively. Lot 1 was fed common ground barley *ad libitum* and lot 2 corn *ad libitum*. In 1895 the test was repeated with smaller and younger pigs. The results are briefly reported.

In 1896-97 a test was made with 44 pigs divided into 9 lots. The lots were fed corn, bald barley, and common barley (whole and ground), with and without skim milk. The test was continued for about 6 weeks. The lots were rearranged during the test, so as to make the comparison as nearly equal as possible. The average results are shown in the following table:

*Results of pig-feeding experiments, 1896-97.*

Foods used.	Number of trials.	Average weight of pigs at beginning of test.	Average daily gain.			Food consumed per pound of gain.	
			Average daily gain.	Grain.	Skim milk.	Grain.	Skim milk.
		<i>Pounds.</i>	<i>Pound.</i>	<i>Pounds.</i>	<i>Quarts.</i>	<i>Pounds.</i>	<i>Quarts.</i>
Whole corn.....	6	71	0.39	2.0	0.7	7.0	1.1
Ground corn.....	5	60	.46	2.4	1.0	5.4	1.1
Whole bald barley.....	8	88	.58	2.3	1.2	5.0	1.3
Ground bald barley.....	5	67	.74	2.4	.8	3.6	.8
Whole common barley.....	4	68	.49	2.3	.5	5.4	.7
Ground common barley.....	4	47	.70	2.4	1.1	4.3	1.1
Ground corn and barley.....	4	50	.77	2.1	1.0	4.1	.8

The following conclusions were drawn: Grinding increased the value of bald barley one-half, common barley one-twelfth, and corn one-fifth. The most rapid gains were made with ground bald barley. Ground corn and ground common barley had about the same feeding value, the barley being slightly superior. A pound of gain required one-half more ground corn than ground barley, and one-third more ground common barley than ground bald barley. Ground common barley and ground corn fed together gave better results than the same grains fed separately.

*Feeding experiments with steers* (pp. 28-30).—A brief account is given of experiments reported in more detail in a previous publication of the station (E. S. R., 8, p. 517).

*Feeding experiments with sheep* (pp. 30-38).—In 1895-'96 a test of 96 days' duration was made with 220 lambs, divided into lots of about 35 each, to compare barley, corn, wheat, beets, and a mixture of barley and corn. All the grains were fed ground. Few details of the experiment are recorded and only the results for barley are reported.

*Results of sheep-feeding experiments, 1895-'96.*

	Food consumed.					Gain in weight per head.
	Hay.	Barley.	Corn.	Wheat.	Beets.	
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
Lot 1 .....	300	86				27
Lot 2 .....	294		86			23
Lot 3 .....	321				375	22
Lot 4 .....	227			77	218	26
Lot 5 .....	181	32	56			26
Lot 6 .....	191	32	56			26

Wheat and common barley have given practically the same results, as have also common barley and corn, there being a slight difference in favor of the corn. Barley and corn fed separately gave somewhat better results than when fed together.

During the winter of 1896-'97 a test, covering 179 days, was made with 440 lambs divided into 10 practically equal lots. All the lots were fed alfalfa hay, and one lot also received silage. The grains used were common barley, bald barley, and corn, fed ground and unground. The test was divided into 4 periods, of 47, 92, 21, and 20 days, respectively. During the first period lots 1 to 4 were given hay only, and lots 5 to 10 received a small amount of grain in addition to hay. In the second period all the lots were fed grain in amounts not exceeding a pound. In the third period all the lots except 2, 9, and 10 were given 1½ lbs. of grain per day, the lots enumerated consuming somewhat smaller amounts. During the fourth period all the lots were fed whole corn. The results are briefly summarized in the following table:

*Results of sheep-feeding experiments, 1896-'97.*

	Food consumed.			Gain in live weight.
	Hay.	Grain.	Silage.	
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
Lot 1 (ground corn) .....	16, 969	4, 690		38
Lot 2 (ground bald barley) .....	18, 183	4, 279		33
Lot 3 (whole bald barley) .....	17, 996	4, 618		38
Lot 4 (ground corn and barley) .....	17, 442	4, 618		37
Lot 5 (silage and ground corn) .....	8, 946	3, 181	19, 926	40
Lot 6 (whole corn) .....	14, 570	5, 220		44
Lot 7 (ground corn) .....	15, 216	5, 176		42
Lot 8 (whole common barley) .....	16, 856	5, 173		40
Lot 9 (ground common barley) .....	15, 637	5, 047		38
Lot 10 (ground bald barley) .....	13, 958	4, 767		38

Feeding grain from the start produced better and cheaper gains than feeding hay for 6 weeks before grain was fed. Better and cheaper gains were made on whole grain than on ground grain. Corn, ground

or unground, gave better returns than common barley. When fed in moderate amounts, slightly better gains were made on bald barley than on corn. Corn and bald barley mixed did not yield better returns than corn alone.

**Feeding separator milk to calves, C. F. CURTISS** (*Iowa Sta. Bul.* 35, pp. 759-768, figs. 6).—In continuation of work previously reported (*E. S. R.*, 4, p. 739; 6, p. 453), a test lasting 74 days was made with 3 lots of 4 calves each to study the comparative value of linseed meal, oatmeal, corn meal, and flaxseed, and corn meal fed with separator skim milk. Each lot received about 3,760 lbs. of separator skim milk and 1,480 lbs. of hay. In addition, lot 1 was fed 429 lbs. of linseed meal; lot 2, 605 lbs. of oatmeal; lot 3, 59 lbs. of flaxseed and 538 lbs. of corn meal; and lot 4, 601 lbs. of corn meal. The lots were kept in well ventilated sheds with yards connecting. Salt and water were always accessible. The foods consumed, gains made, and cost per pound of gain are shown in the following table:

*Summary of results of calf feeding.*

	Nutritive ratio of ration.	Total gain.	Average daily gain per head.	Dry matter eaten per pound of gain.	Cost of feed per pound of gain.
		<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Cents.</i>
Lot 1 (linseed meal) .....	1:3	483	1.63	4.13	2.5
Lot 2 (oatmeal) .....	1:4.1	498	1.68	4.31	2.2
Lot 3 (flaxseed and corn meal) .....	1:4.8	489	1.65	4.32	2.3
Lot 4 (corn meal) .....	1:4.9	509	1.72	4.16	2.0

The results obtained are compared with those of the previous tests.

"In each of the 3 experiments conducted by this station linseed meal has given lower and more expensive gains, and has been in every way less satisfactory than either oatmeal, or corn meal and flaxseed. . . . The results indicate that pure corn meal is superior to pure linseed meal for feeding to calves in combination with skim milk. . . .

"While the results of these experiments are contrary to prevailing opinion concerning the relative value of these feeds, it is not unnatural or in any way unreasonable that the carbonaceous grains should be more suitable for feeding with skim milk than a highly nitrogenous product like linseed meal."

**Steer feeding experiments, VI, C. C. GEORGESON, F. C. BURTIS, and D. H. OTIS** (*Kansas Sta. Bul.* 67, pp. 55-73).—The comparative value of corn and red and white Kafir corn was tested with 15 steers divided into 3 lots of 5 each. The steers were three-year-old grade Herefords or grade Shorthorns. All were dehorned, 5 of them a short time before the test began. From the time of their arrival at the station (about the first of October) until about the middle of the month the steers were pastured on a good meadow pasture, but were given no grain. From this time on until the beginning of the test proper they were fed a mixture of equal parts of corn and red and white Kafir corn finely ground in increasing quantities until 16 lbs. per head daily was fed. During the latter part of the preliminary period the steers were

kept in a yard to accustom them to the experimental conditions of the test proper.

The experiment proper began November 3 and closed April 27. Lot 1 was fed corn meal, lot 2 red Kafir corn meal, and lot 3 white Kafir corn meal. In every case 16 lbs. of grain was fed per head daily, since it was found that a larger amount than this was not eaten up clean. Each lot was fed 100 lbs. of well-cured Kafir corn fodder, the uneaten residue being weighed back in every case. A little corn fodder and, near the close of the experiment, a little alfalfa hay were also fed. The financial statement is based on corn meal and Kafir corn meal at 30 cts., corn stover and Kafir corn stover at 12½ cts., and alfalfa at 20 cts. per 100 lbs. The steers were purchased for \$3.52 and sold for \$4.50 per hundred. The details of the experiment are reported in full. The average results were as follows:

*Results of feeding steers.*

	Average weight at beginning.	Average daily gain in weight.	Grain eaten per pound of gain.	Coarse fodder eaten per pound of gain.	Cost per pound of gain.	Profit per head.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Cents.</i>	
Lot 1 (corn meal) .....	1,036	1.86	9.97	5.69	3.73	\$9.52
Lot 2 (red Kafir corn meal) .....	1,021	1.71	10.86	6.88	4.15	8.99
Lot 3 (white Kafir corn meal) .....	1,025	1.78	10.41	6.92	4.01	8.40

Practically the same gains were made by the 3 lots.

In order to determine the percentage undigested of the 3 grains the authors collected the manure from each lot for 33 days at the beginning of the experiment. Each day the manure was washed with water and constantly agitated. "This caused the manure particles to rise to the top and float away with the water, while the undigested meal settled to the bottom. Only an insignificant portion of the finest of the meal could be lost by this treatment." The amount of grain undigested is shown in the following table:

*Digestibility of grain fed to steers.*

	Grain eaten.	Weight (dry) of grain washed from manure.	Grain undigested.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Per cent.</i>
Lot 1 (corn meal) .....	2,982	162.77	5.46
Lot 2 (red Kafir corn meal) .....	3,008	340.36	11.27
Lot 3 (white Kafir corn meal) .....	3,008	425.09	11.13

The corn meal was better digested than either the red or white Kafir corn meal. The authors remark that, although the grains were all ground in the same mill, the corn was more finely ground than the Kafir corn.

*Pigs following the steers.*—To study the comparative value of the droppings from the different lots, 7 pigs followed each lot of steers from December 15 until the close of the test. The amount of grain fed to the pigs in addition is recorded. They were fed the same grains as the steers which they followed. At the beginning the average weight of the pigs following the different lots was 166, 168, and 169 lbs., respectively. On the basis of the undigested grain as determined above the food consumed, the gains made, and the food consumed per pound of gain were as follows:

*Results of experiment with pigs following steers.*

	Grain eaten.	Feed available in manure.	Gain in weight.	Food consumed per pound of gain.
	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>	<i>Pounds.</i>
Lot 1 (corn meal) .....	2,520	705	635	5.07
Lot 2 (red Kafir corn).....	2,520	1,475	698	5.72
Lot 3 (white Kafir corn) .....	2,480	1,842	725	5.96

It is evident from the table that, though the pigs were fed practically the same amounts of grain, the gains made vary with the amounts found in the manure. In the authors' opinion the experiment proves that pigs can utilize Kafir corn feed in the manure and bring out the value in pork in about the same ratio of values that exists between corn and Kafir corn.

The pigs were not all sold, but from available data it was calculated that there would have been a profit of \$7.10 for lot 1, \$10.12 for lot 2, and \$11.21 for lot 3. Records were kept of the mean daily temperature of the yards throughout the whole experiment.

**Feeding lambs,** C. F. CURTISS and J. W. WILSON (*Iowa Sta. Bul.* 35, pp. 717-719, figs. 18).—In continuation of work previously reported (*E. S. R.*, 9, p. 84) the authors made a feeding experiment with 81 wether lambs of the following breeds: Southdown, Shropshire, Oxford, Suffolk, Lincoln, Leicester, Cotswold, Dorset, and Merino, and 10 Shropshire ewe lambs.

The lambs were divided into 7 lots of 9 each, 1 lot of 10, and 1 lot of 8. Most of the lambs were purchased in Canada and arrived at the station during July and August. They were dipped soon after their arrival and put on a timothy and blue grass pasture, and given a light ration of oats and bran in addition. The lambs were given worm powders, which were found to be more of a preventive than a remedy. The general conditions were the same as in the previous experiment. The experiment proper, which was preceded by a preliminary period of 15 days, began December 16 and continued 106 days, the conditions being the same throughout the whole time.

The lambs were fed all they would eat of a mixed grain ration with roots and hay. During the early part of the test a little green clover

was fed. For the first 15 days the grain ration consisted of bran, oats, and corn, 1:2:2. For the next 35 days the following mixture was fed: Linseed meal, bran, oats, and corn, 1:2:8:8. During the remainder of the test the linseed meal was increased two-fifths. At the beginning of the test the lambs ate 1 to 1½ lbs. of grain daily and at the close from 1½ to 2¼ lbs.

The financial statement is based on bran and oats at 35 cts., shelled corn and hay at 20 cts., linseed meal at 90 cts., roots at 5 cts., and cabbage at 10 cts. per 100 lbs.

The details of the experiment are given in tabular form. The results are summarized in the following table:

*Results of feeding different breeds of lambs.*

	Food consumed.						Average daily gain per head.	Dry matter eaten per pound of gain.	Cost of food per pound of gain.
	Corn and oats.	Bran.	Linseed meal.	Hay. <sup>1</sup>	Roots.	Cabbage.

<sup>1</sup> Including a little green clover.

The ewe lambs were light eaters and made comparatively small gains, but the cost of production was about the same as the average of the wethers.

“The marked increase in the cost of feed per pound of gain during the experiment was apparently due to the fact that the ewe lambs took on fat rapidly and were more nearly finished during the latter part of the period than the other lots. This distinction between the sexes has been observed in all of the experiments made at this station, including both cattle and sheep. On the market the ewes sold 5 cts. higher than the wethers of the same breed, and in the slaughter test they dressed 1.67 per cent more net carcass. On the block they showed slightly more fat, but their fine bone and plump, neat carcasses made them attractive and profitable. The price put on them by the buyers clearly indicates that there is no discrimination against ewe lambs, as there formerly was against the heifer. It should be mentioned incidentally, however, that after the ewes are a year old they are not as desirable as wethers, owing to the fact that the joints do not break as readily. Free clean breaking of the front pastern is the test applied by meat dealers to distinguish between a lamb and a sheep. One that breaks is a lamb; one that does not is a sheep, regardless of actual age.”

As regards gains made the relative rank of the breeds was the same in this as in the preceding experiment.

"The Cotswolds again lead, with the Lineolns and Leicesters closely following. The general average for the Southdowns and Shropshires is the same, and their rank is next to the long-wooled breeds for economy of production, and in this they are followed closely by the Dorsets, and they in turn by the Oxfords and Suffolks. . . . The whole number of lambs, 109 in the first experiment and 91 in the second, not including the ewes, made a total gain of 8,246 lbs. from 69,134 lbs. (dry matter) of feed—a rate of 1 lb. of gain for 8.38 lbs. of dry matter in the feed consumed, and an average of 0.448 lb. per head daily for the entire lot. The total gain of 8,246 lbs. was made at a cost of \$245.69 for feed consumed, or an average cost of 2.97 cts. per pound for the mutton produced in both experiments. This calculation makes no allowance for the value of the fleece, except as it entered into the gain, nor does it take into account the value of the manure or expense of labor in feeding."

At the close of the test the wethers were sold in Chicago for from \$5 to \$5.75 per hundred, and the ewes for \$5.65. The dressed weight of the wethers was 49.27 to 55.26 per cent of the live weight, and the dressed weight of the ewes 54.55 per cent. A detailed record is given in tabular form of the slaughter test, which shows the net weight of the several parts of the carcass and of the internal organs and their percentage of the whole. The carcasses were cut up and the meats judged by an expert. In his opinion the Southdowns and the Shropshire ewes ranked highest in the value of the mutton; the Oxfords, Lineolns, and Leicesters next, and the Suffolks, Dorsets, and Merinos lowest.

The sheep were not shorn as in the former experiment. The value of the fleece was calculated from the combined weight of pelts and wool.

**Feeding range lambs, C. F. CURTISS and J. W. WILSON** (*Iowa Sta. Bul. 35, pp. 750-758, figs. 4*).—A test was made with 252 range lambs to study the possibilities of profitable feeding under local conditions. The lambs were divided into 4 lots of 63 each, and consisted of the following breeds: Lot 1, Merinos (shorn); lot 2, Cross Wools; lot 3, Down Coarse, and lot 4, Merinos (unshorn). The lambs were purchased November 3. The feeding experiment began December 1 and lasted 110 days. Until the beginning of the feeding trial the lambs were pastured on blue grass and given a light ration of bran and oats morning and evening. They also had access to hay during the night. During the experiment proper they were fed a ration consisting of oats, corn, linseed meal, and bran, with mangel-wurzels and hay in addition. At the beginning of the test the lambs ate less than  $\frac{1}{4}$  lb. of the mixed grain per day, at the end of the first month only  $\frac{1}{3}$  lb., while the hay consumed per day was at first as high as  $3\frac{1}{2}$  lbs. per head. The amount of hay consumed gradually decreased to about 2 lbs. at the end of the test and the amount of grain increased.

The financial statement is based on the following prices per 100 lbs.: Bran and oats, 35 cts.; hay and shelled corn, 20 cts.; linseed meal, 90 cts., and roots, 5 cts.

The foods consumed and the gains made by the different lots are given in full. The average weights of the lambs in the different lots at the beginning were as follows: Lot 1, 46.9 lbs.; lot 2, 52.8 lbs.; lot 3,

53.8 lbs., and lot 4, 53 lbs. The average gains made were 29.2 lbs., 28.3 lbs., 28.9 lbs., and 27.6 lbs., respectively.

"It will be observed that while these lambs have not made as large gains as the pure bred and have required more feed (dry matter) for a pound of gain, they have nevertheless produced very creditable gains at unusually low cost for feed consumed. The greater amount of feed and lower cost for a pound of gain by these lambs, in comparison with the pure bred, seems like an inconsistent result. This apparent inconsistency, however, is doubtless due to the variation in the rations consumed.

"The pure-bred lambs ate relatively much less hay and correspondingly more grain, consequently the results with respect to economy of production between the pure bred and the range lambs are not directly comparable. The hay fed to the range lambs was alfalfa a part of the time, and clover and timothy of good quality the remainder. On account of their taking readily to a liberal allowance of hay and eating sparingly of grain, a ration of this kind seemed best suited to these lambs, while the pure bred were capable of utilizing a heavier grain ration with correspondingly less hay. Both lots of lambs had all the grain they would eat during the last sixty days."

The lambs were sold in Chicago at from \$4.70 to \$5.25 per hundred. The percentage of dressed weight of the several lots was as follows: Lot 1, 55.9; lot 2, 53.5; and lots 3 and 4, 52.8. The net profit per head for the 4 lots was 42 cts., 75 cts., 87 cts., and 70 cts., respectively.

"While these lambs are not of the class that farmers could afford to raise on high-priced lands, they can, nevertheless, be fed at a good profit under conditions similar to those reported in this bulletin."

**Is skim milk or buttermilk best for pigs?** F. E. EMERY (*North Carolina Sta. Bul.* 143, pp. 170-175).—A test of the comparative value of skim milk and buttermilk was made with 12 pigs divided into 4 lots of 3 each. Lots 1 and 2 were fed sweet skim milk and middlings, lot 2 receiving 25 per cent more milk than lot 1. Lots 3 and 4 were fed buttermilk and middlings, lot 4 receiving 25 per cent more buttermilk than lot 3. The pigs had access during the test to a mixture consisting of hard-wood ashes, salt, copperas, black antimony, sulphur flowers, and charcoal. The pigs were farrowed early in September. The boars were castrated before weaning. After weaning, until the experiment proper began, the pigs were fed a mixture of wheat middlings, corn, bran, and linseed meal. The experiment proper began December 26 and lasted until March 30. The food consumed and gains made are recorded. During the whole test the pigs in lots 1, 2, and 3 gained from 17 to 19 oz. per day, and the pigs in lot 4 made an average gain of about 14.5 oz. per day. Reckoning the middlings at 85 cts. per 100 lbs. and the pigs at 4 cts. per pound live weight or 5 cts. per pound dressed weight (it being assumed that the dressed weight was 80 per cent of the live weight), the value of 100 lbs. of skim milk and buttermilk was calculated. The results of the experiment are shown in the following table:

*Results of feeding pigs.*

	Food consumed per pound of gain.			Value of milk per 100 pounds.
	Wheat mid-dlings.	Skim milk.	Butter-milk.	
	Pounds.	Pounds.	Pounds.	Cents.
Lot 1.....	3.43	5.12	.....	20.80
Lot 2.....	3.26	6.12	.....	20.80
Lot 3.....	3.51	.....	5.10	19.78
Lot 4.....	2.78	.....	5.72	28.62

The pigs were slaughtered at the close of the experiment or shortly after. Brief statements are made concerning the slaughter test.

**Report of the poultry division, C. O. FLAGG** (*Rhode Island Sta. Rpt. 1896, pp. 354-362*).—Analyses (food constituents and mineral matter) are reported of a number of poultry foods as follows:

*Composition of poultry foods.*

	Food constituents.					Mineral matter.					
	Water.	Protein.	Fat.	Nitrogen-free extract.	Fiber.	Ash.	Calcium oxid.	Magnesium oxid.	Potassium oxid.	Phosphoric acid.	Insoluble matter.

In continuation of previous work (E. S. R., 8, p. 622) experiments were made in cross breeding geese, which are briefly reported. A number of the geese raised were fattened and sold and others were exhibited. The first geese were sold when 97 days old; the best were the result of crossing an Embden gander with African geese; their average live weight was 15 lbs. 3½ oz., and the average dressed weight 13 lbs. 7½ oz. The Embden-Toulouse cross also developed large geese, but they did not grow as rapidly as the Embden-African.

"It appears to be desirable to use a white bird for one parent in making a cross, in order, so far as possible, to grow white, pied, or light-colored birds for market, because they pick much easier, usually have a whiter flesh, and are handsomer in appearance. These are important points, and affect the price when the bird comes on the market. Entirely dark birds, as Africans, Toulouse, or Brown Chinas, have black pinfeathers, which make them hard to pick when dressed as green geese. If they are not thoroughly taken out they show on the dressed bird very distinctly, and injure the appearance, while white pinfeathers are much less objectionable. The color of the flesh, aside from the effect of the black or white pinfeathers is, as

a rule, in favor of the white or light-colored bird. Toulouse, Brown China, and African geese, unless very fat, are generally of a darker appearance when dressed than Embdens or White Chinas."

The importance of an abundant supply of pasturage for geese is insisted upon and the need of supplementing any lack in this direction by suitable soiling crops. Grass seems to be preferred by geese to all other green crops. When pastured on oats and peas the oats were always eaten before the peas. Cabbage, turnips, and sweet corn are regarded as excellent soiling crops. Sweet corn sufficiently advanced to be in the roasting-ear stage will be almost or quite devoured when fed at night. Sorghum and dwarf Essex rape were found to be very satisfactory green crops.

**Blood-molasses feed for horses**, E. J. HANSEN (*Ugeskr. Landm.*, 43 (1897), No. 50, pp. 672-674).—The process of manufacturing the molasses feed is explained in detail. The feed is a mixture of 250 parts of blood, 200 parts beet molasses, 200 parts Scotch oat bran, and 100 parts "starch-free maize meal." Analysis shows its composition to be as follows: Water 10.10, protein 19.63 (albuminoids 16.48), ether extracts 2.00, crude fiber 6.32, nitrogen-free extract 55.11, and ash 6.84 per cent. The feed was relished by horses. A blood molasses feed for cattle and one for swine are also manufactured.—F. W. WOLL.

**Composition of hay from mountain pastures**, F. H. WERENSKIOLD (*Tidsskr. Norske Landbr.*, 4 (1897), pp. 427-430).—Six analyses of hay from Norwegian mountain pastures (*säterhö*) are given, and the results discussed and compared with earlier analyses of similar hay and of meadow hay. Of the total protein 61.5 per cent was found to be digestible by the Stutzer-Kühn method. The analyses indicate that the hay from the mountain pastures possesses a higher nutritive value than the cultivated grasses, and perhaps as high value as the cultivated legumes. Their crude fiber content, in connection with the relatively high percentage of moisture which they contain, makes the grasses tender and soft when cured. Such hay may be more palatable to cattle than the rather stiff hay from the common cultivated fodder plants.—F. W. WOLL.

**What the Mexicans eat** (*Dietet. and Hyg. Gaz.*, 14 (1898), No. 3, pp. 144-146).—An abstract of a paper by F. Semeleder read before the section of physiology and dietetics of the American Medical Association at its last meeting. A number of typical foods and food products are enumerated and some are described.

**Boarding houses and clubs for working women**, MARY S. FERGUSON (*U. S. Dept. Labor Bul.* 15, pp. 141-196).—A number of boarding houses and clubs conducted under the auspices of charitable or other organizations are described and discussed. Statistics which include cost of food are given of 90 institutions.

**The composition of different kinds of flour used in Italy**, G. FABRIS and O. SEVERINI (*Ann. Gabelle. Roma*, 3, p. 27; *abs. in Bul. Soc. Chim. Paris*, 20 (1898), No. 2, pp. 109, 110).—A large number of Italian flours were examined. A classification is given based on the ash content. Thus, first-class flour shows an ash content of about 0.6 per cent, medium 0.6 to 1 per cent, and ordinary above 1 per cent.

**Flour in China and Japan** (*U. S. Consular Rpts.*, 1897, Dec., pp. 519-528).—Statistics as to the amount of flour used in cities in China and Japan and its source. The bread and similar products made from flour in a number of cases are described.

**Adulteration of wheat flour**, A. J. WEDDERBURN (*U. S. House of Rep.*, 55, Congress, 2. Session, Doc. 309, pp. 42).—The author, under the direction of the Division of Chemistry of this Department, has gathered from a number of manufacturers and millers information concerning adulteration of flour.

**The use of horse flesh as food** (*Rev. Sci.*, 4. ser., 8 (1897), No. 24, p. 762).—The use of horse flesh in different countries is briefly discussed, and its composition compared with that of beef, mutton, and pork.

**Consumption of food products in the United Kingdom** (*Jour. Bd. Agr.* [London], 4, No. 12, pp. 293-300).—The article gives statistical information of the kind and amount of food consumed.

**Mushrooms—their economic and pathological relations** (*Dietet. und Hyg. Gaz.*, 14 (1898), No. 3, pp. 147-149).—A general article quoted from an address by H. G. Piffard.

**Prickly pear** (*Agr. Gaz. New South Wales*, 9 (1898), No. 1, pp. 38-40).—This article, quoted from a paper by P. Gennadius, describes the culture of the prickly pear, the different varieties, and the use of the fruit as food and the plant and fruit as a feeding stuff.

**Ensilage up to date**, J. L. THOMPSON (*Agr. Gaz. New South Wales*, 9 (1898), No. 1, pp. 68-106, figs. 8).—Opinions of many writers and reports of experiments with silage are quoted, and directions given for making and filling silos, silage stacks, etc.

**The utilization of beet leaves**, J. P. WAGNER (*Jour. Agr. Prat.*, 2 (1897), No. 38, pp. 448-450).—The value of beet fodder and silage is discussed.

**Soy beans as food and fodder**, S. H. ANGELL (*U. S. Consular Rpts.*, 1897, Dec., pp. 551, 552).—A translation of a general article by H. Fortune.

**Composition of the straw of oats, wheat, and rye**, BALLAND (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 25, pp. 1120-1122).

**Analyses of potatoes**, B. H. ILTE (*West Virginia Sta. Rpt.* 1896, pp. 50-57).—Determinations of specific gravity, total solids, water, starch, protein, fiber, fat, other carbohydrates, and ash soluble and insoluble in water in over 200 samples of potatoes are reported, and the methods of analysis used are described. No average or summary is given.

**Studies of Norwegian potatoes, with special reference to starch content**, J. SEBELIEN (*Tidsskr. Norske Landbr.*, 4 (1897), Nos. 5, pp. 209-225; 6, pp. 259-278).

**Feeding sprouted grains**, O. KELLNER (*Sach's Landw. Ztschr.*, 45 (1897), No. 13, p. 58).—The inferior value of sprouted grain on the basis of composition is pointed out.

**The digestibility of dried maize used for brewing** (*Deut. Landw. Presse*, 24 (1897), No. 76, p. 699).—Quoted from an article by B. Schulze in *Jahresber. Agr. Chem. Vers. Stat. Breslau*, 1896.

**Skim-milk bread and its assimilation by man**, H. REPSTEINER and W. SPIRIG (*Korbl. Schweiz. Aerzte*, 25, pp. 705-710; noted in *Jahresber. Thier. Chem.*, 25 (1895), p. 451).—Experiments were made which, in the authors' opinion, showed that bread made with skim milk was extremely well assimilated. They recommend the use of skim milk (and buttermilk) in bread making.

**Preservation of eggs**, J. H. THIÉRIOT (*U. S. Consular Rpts.*, 1897, Dec., pp. 563, 564).—A report is given of tests in Germany of 20 methods of preserving eggs. The most satisfactory methods were varnishing the eggs with vaseline and preserving them in linewater or a solution of water glass. The latter was preferable since varnishing the eggs with vaseline takes considerable time and treating them with linewater is likely to give the eggs a disagreeable odor and taste. "There is, however, one drawback with eggs preserved in a solution of water glass, viz, that the shell easily bursts in boiling water. This may be avoided by cautiously piercing the shell with a strong needle."

**Peat dust for preserving eggs** (*Landw. Centbl. Posen*, 25 (1897), No. 34, p. 209).—A note on the successful preservation of eggs by burying them in peat dust.

**Food preservatives and butter increasers**, G. W. CAVANAUGH (*New York Cornell Sta. Rpt.* 1896, pp. 459-464).—A reprint of Bulletin 118 of the station (E. S. R., 8, p. 421).

**On preservative salts**, E. HOTTER (*Ztschr. Nahr. Untersuch. u. Hyg.*, 11 (1897), No. 20, pp. 334, 335).—A discussion of the subject with analysis of a preservative salt.

**Supplemental report of the dairy and food commissioner**, L. WELLS (*Pennsylvania Dept. Agr. Rpt.* 1896, p. 466).—Examinations of a number of samples of vinegar, baking powder, and miscellaneous foods and condiments are reported, and a court decision in favor of the pure-food law of the State is cited.

**Cider vinegars of Pennsylvania**, W. FREAR (*Pennsylvania Dept. Agr. Bul.* 22, pp. 27).—Vinegar and vinegar making is discussed and a number of analyses of vinegar from different localities in Pennsylvania are reported. Directions for testing vinegar and a test for acidity suited to the needs of farmers are given.

**Cider vinegars of Pennsylvania**, W. FREAR (*Pennsylvania Dept. Agr. Rpt.* 1896, pp. 493-513).—This is a reprint of Bulletin 22 of the Pennsylvania Department of Agriculture (see above).

**Fruit vinegar**, J. JETTMAR (*Ztschr. Nahr. Untersuch. u. Hyg.*, 11 (1897), No. 21, pp. 345, 346).—A discussion of fruit vinegars, with report of analyses of 2 samples.

**The value of meat extract as a condiment**, C. VOIT (*München. Med. Wchenschr.*, 1897, No. 9; *abs. in Hyg. Rundschau*, 7 (1897), No. 24, p. 1263).

**The examination of American lard**, H. SCHLEGEL (*Forsch. Ber. Lebensmtl.*, 4 (1897), No. 12, pp. 350, 353).

**On the establishment of compulsory examination of meat in the States of the North German Federation**, R. OSTERTAG (*Ztschr. Fleisch u. Milchhyg.*, 8, No. 2, pp. 21-27).

## DAIRY FARMING—DAIRYING.

**Eighth and ninth years' feeding experiments with milch cows**, F. FRIIS (*Ber. K. Vet. Landbohöjskoler Lab. Landökon. Försög* [Copenhagen], 1897, pp. 107).—This is a continuation of the Danish cow feeding experiments made by the experiment station at Copenhagen (E. S. R., 4, p. 601; 6, pp. 588, 657; 8, p. 255). The report covers the experiments of 1895 and 1896, which were made on the same general plan as the earlier ones. The main results of the experiments of 1895, which were on the comparative value of mixed grain (barley and oats) and wheat for milk and butter production, were given in an earlier publication of the station and have already been abstracted (E. S. R., 8, p. 255).

The experiments of 1896 were conducted on 4 different estates with 152 cows in all, their purpose being to study the value of molasses feed as compared with mixed grain (barley and oats). The molasses feed was made up of one half beet molasses, three-eighths wheat bran, and one-eighth palm-nut meal. The cows on each estate were divided into 3 even lots of at least 10 head each. One of these lots (B) received the same feed throughout the experiment, viz, equal parts of mixed grain and molasses feed. The feed of the 2 other lots (A and C) was the same as that of lot B during the preliminary and the post-experimental periods, but during the experimental period proper lot A had mixed grain only and lot C molasses feed. The report gives detailed statements and tables as to the rations fed, live weights of animals, yield and composition of milk produced on each estate, and the composition

of the various cattle foods used. The following summary includes the more important results:<sup>1</sup>

*Molasses feed vs. mixed grain for cows.*

	Yield of milk.			Fat content of milk.			Live weight of cows.		
	Lot A (mixed grain).	Lot B (grain and molasses feed).	Lot C (molasses feed).	Lot A (mixed grain).	Lot B (grain and molasses feed).	Lot C (molasses feed).	Lot A (mixed grain).	Lot B (grain and molasses feed).	Lot C (molasses feed).
	<i>Lbs.</i>	<i>Lbs.</i>	<i>Lbs.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Lbs.</i>	<i>Lbs.</i>	<i>Lbs.</i>
Preliminary period.....	27.3	27.4	27.4	3.25	3.23	3.26	969.0	958.0	963.0
Experimental period.....	23.7	23.7	23.4	3.16	3.12	3.15	970.7	959.5	965.0
Supplementary period....	21.8	21.6	21.6	3.27	3.21	3.27	969.2	959.0	964.6

The results of the experiments indicate that molasses feed and mixed grain (barley and oats) possess the same feeding value, pound for pound, for milch cows when fed in similar food combinations as in these experiments, viz, with oil cakes, roots, hay, and straw. Even when 3.3 lbs. of molasses feed was fed with 55 lbs. of mangel-wurzels per day, no deleterious effect could be traced in the digestion of the cows.

*Sugar-beet residue and molasses feed vs. mixed grain.*—In a single experiment at the Ourupgaard estate during 1895-'96 with 28 cows divided into 2 even lots, 2 lbs. of mixed grain, 2 lbs. of molasses feed, and 20 lbs. of sugar-beet residue were fed to 1 lot, and 2 lbs. of molasses feed and 44 lbs. of beet residue were fed to the other lot. All the cows received oil cakes and hay in addition. Hence 24 lbs. of sugar beet residue was compared with 2 lbs. of mixed grain (barley, oats, with a little peas, grown together). The yield and composition of the milk produced and the weight of the cows indicated that the feeds mentioned were of about similar value, in the proportions fed.

*The effect of food on quality of milk.*—The general conclusion on this point to which these Danish cow-feeding experiments have led is given as follows: In the comparative feeding experiments with milch cows, now continued during 9 consecutive years, in which about 2,500 cows divided into 218 lots on 12 estates in different parts of our country have been included, it has constantly been found that the changes made in the system of feeding the different lots have been practically without effect upon the chemical composition of the milk. In these experiments, barley and oats have been fed against roots, oil cakes, wheat bran, wheat and molasses feed; mixed grain and oil cakes have been fed against roots, and grain and roots have been fed in addition to the regular rations given. It must be remembered, however, that the changes in the feed were never so great as to make the resulting rations abnormal (according to Danish feeding practice).—F. W. WOLL.

**Comparative effect of some rations fed to milch cows, F. E. EMERY** (*North Carolina Sta. Bul. 143, pp. 161-169*).—The results are

<sup>1</sup>The Danish pound = 1.1 lbs. avoirdupois.

given of trials with 4 cows in 4 periods of 2 weeks each. In these trials cotton-seed meal and hulls was fed against corn shucks and a mixed grain ration; and corn and soy bean silage with cotton-seed meal and bran was fed against 2 different grain rations containing sweet potatoes. The author makes the following deductions:

“(1) The ration of sweet potatoes, raw cotton seed, pulled [corn] fodder and cow-pea meal gave better results for cow Dora McKee than did corn and soy-bean silage and cotton-seed meal, with wheat bran mixed in ratio of 1 to 2, by weight.

“(2) The corn and soy-bean silage, with cotton-seed meal and wheat bran, gave a better result with cow No. 5 than did sweet potatoes and corn shucks, with a mixture of cotton-seed meal, corn meal, and cowpea meal mixed in the proportions of 6, 2, and 1.

“(3) Cotton-seed hulls and meal for butter production leads corn shucks and wheat straw with corn meal, ground wheat, and cotton-seed meal mixed in proportions of 2, 3, and 5. The latter made the most milk, however. Cow No. 19 lost in the last period so much, the result was evened up and became indeterminate.”

**Summary of record of milk and butter production of station herd, 1895 and 1896, F. E. EMERY** (*North Carolina Sta. Bul. 113, pp. 176-187*).—This is a record for 14 cows in 1895 and 16 cows in 1896, showing the yield and fat content of milk, calculated yield of butter, amount and cost of food consumed, net profit or loss, etc. In 1895 8 of the 13 cows for which financial data are given either gave no profit or were kept at a loss ranging from \$2.26 to \$13.53; and in 1896 8 of the 16 cows were kept at a loss ranging from 92 cents to \$15.86. The author explains that some of the cows “have not been culled out before the end of this year’s record in order to give time, after the trouble from epizootic abortion was over, for cows to assume a normal flow of milk, thus avoiding hasty judgment and consequently erroneous work.”

**Milk: Its value as a food and studies which suggest a different method of sale, E. B. VOORHEES and C. B. LANE** (*New Jersey Stas. Bul. 123, pp. 19*).—The value of milk as a nutritious food of moderate cost is pointed out, and the variations in the quality of milk owing to a variety of causes are discussed.

Observations are reported on the station herd of 28 cows, mostly of mixed breeding. The cows were fed so as to keep them up to their full capacity without attempting to force a large yield. Samples of the milk of each cow were tested weekly. The average monthly composition of the milk of the herd for 1 year and the variations in the composition of the milk of individual cows are given. These show that, while there were wide variations in the milk of individual cows, the range being from 2.6 to 8.3 per cent of fat in the month of December, the composition of the mixed milk of the herd was remarkably uniform, the monthly average ranging from 4 to 4.4 per cent during the year.

“In other words, it appears, from the study of this herd, which is fairly representative of good herds throughout the State, that, so far as uniformity in composition of the daily mixed milk is concerned, its sale on the fat basis would have been entirely practicable.”

Observations were also made on the effect of the period of lactation and the character of the food. Although individual animals varied greatly, "in the first 5 months the decrease in total milk flow from month to month is proportionately greater than the decrease in the total fat, and hence the average percentage of fat in the milk gradually increases, so that in the fifth month it is 0.5 greater than the average percentage in the first month." For the remaining 3 months the decrease in milk yield and in total fat were relatively the same.

"The influence of the period of lactation upon the composition of milk, while varying with individual animals, is, therefore, for herds of reasonable size, practically limited to the first 5 months. Hence the main point to observe in attempts to secure uniformity in composition is to evenly distribute the fresh cows introduced into the herd throughout the different months of the year rather than to have them all introduced during any 1, 2, or 3 months."

The experiments on the effect of food included 4 lots of 2 cows each. The effect of substituting silage for dried corn fodder and of adding sugar beets and potatoes with a full ration, limited ration, and no grain was studied in periods of 5 or 12 days' duration.

"While the results of these experiments as a whole confirm the view now generally held by careful observers, viz, that the character and quantity of food influence the flow rather than the composition of milk, a temporary decrease in fat was noticed when animals were changed from a dry to a succulent ration and one much richer in digestible carbohydrates (sugar)."

In conclusion the author urges that milk should be sold on the basis of its fat content; "that is, from the food standpoint the retail price should vary with the variation in composition in order that the consumer may get what he pays for and the producer may be paid for what he delivers." The author believes that the results of his investigations show that this is entirely practicable as far as the dairyman is concerned, and is engaged in devising a system of inspection suited to this plan.

**A flavor-producing micrococcus of butter**, S. C. KEITH (*Tech. Quart.*, 10 (1897), pp. 247, 248, figs. 2; *abst. in Jour. Roy. Micros. Soc. [London]*, 1897, No. 5, p. 430).—A micrococcus that produces a butter flavor and aroma when grown on milk or cream has been isolated by the author and designated as *Micrococcus butyri-aroma-faciens*. The micrococcus is characterized by usually occurring in pairs, by being nonmotile, measuring from 0.5 to 1  $\mu$  in size, and by growing well at 37° and even at 20° C. It is aerobic and liquefies gelatin slowly. On agar its growth is white and abundant. Milk is not coagulated by it, but is given a slightly sour, pleasantly aromatic butter flavor. The reaction of the milk is acid.

**Pasteurization of milk**, C. E. MARSHALL (*Michigan Sta. Bul.* 147, pp. 21-48, figs. 3).—The object of this work was to study certain microorganisms found to be resistant to pasteurization. A new form of sterilizing apparatus is described, consisting of a tall can with a cover, stirring apparatus, and a faucet at the bottom for drawing off the milk. The can is placed in a jacket and surrounded by live steam.

In each of 26 experiments 2 bottles of the pasteurized milk and 2 bottles of the same milk un-pasteurized were taken as samples, one set being tested for acidity and the resistant bacteria and the other set being kept until it spoiled. The data for these samples are given. From the pasteurized milk 39 varieties were isolated and studied. The characteristics of 19 varieties are given, since these are believed to be representative of the whole. The source of these resistant bacteria was studied by making numerous plate cultures of the dust in the air of the stable, the animal, etc. From these bouillon cultures were made of the different kinds of bacteria, and these cultures were pasteurized. Of those which resisted pasteurization 2 were from the dust of the stable, 2 from the dirt from the cow, 1 from the dairy, and 3 from the first part of the milking.

As to the effect of these resistant bacteria on the milk after pasteurization, it was found that some only curdled the milk, some peptonized the casein, some did both, while others produced no perceptible change in the milk.

A special experiment on the thermal death point of tubercle bacilli showed that heating the milk containing them at 68° C. for 20 minutes destroyed the bacilli, so that the milk had no injurious effect when inoculated into guinea pigs. A study of the thermal death points of the resistant bacteria showed that 17 of the 19 forms were not killed by a temperature of 80° C. for 20 minutes; 6 remained alive after heating the same time at 90° C., and 1 at 96° C., but all were killed by boiling 20 minutes. The effect of sudden cooling after pasteurization upon 6 of the resistant varieties was studied in a series of tests on bouillon cultures of these bacteria. In each case one culture was cooled suddenly to 8° C. and another allowed to cool gradually to the temperature of the room, the time required for development being noted in each case.

“In this work 10 cultures of the suddenly cooled exceeded the time of development of the non-cooled; 12 cultures of the non-cooled or cooled gradually exceeded the time of development of the cooled; 6 cultures of the suddenly cooled developed in the same time as the non-cooled. Sudden cooling seems to have no effect on the time of development.”

The restraining influence of keeping at a low temperature on development was shown in trials with the same 6 species. Six miscellaneous micro-organisms were treated in the same way but not subjected to pasteurization. Here it was noticed that the time of development was retarded several days by placing them in the refrigerator. The effect of continued heat in restraining development was illustrated in trials with the 6 same cultures. When the 6 cultures were pasteurized and then kept in a refrigerator very few of the germs developed in 45 days.

In conclusion, remarks are made on the value of pasteurization, especially in preventing contagious diseases and intestinal disorders of young children.

**Quick and slow ripening of cream**, G. L. MCKAY and G. H. ECKLES (*Iowa Sta. Bul.* 35, pp. 820-822).—Nine trials were made, beginning the

middle of May, in each of which 400 lbs. of cream were thoroughly mixed and then divided into two portions, one being cooled at once by the use of ice to about 55° F. and after 3 hours heated to 65° and ripened, and the other not cooled but ripened at a temperature of 70 to 75°. Both lots of cream were ripened to about the same degree of acidity. The butter was scored by a Chicago merchant. "The scores from the quick ripened averaged almost exactly the same as those from the slow ripened. What difference there was in scores followed the acidity and not the difference in the method of ripening." Several advantages of quick ripening are noted.

**Butter colors**, C. B. COCHRAN (*Pennsylvania Dept. Agr. Bul. 13*, pp. 8).—The nature and the toxic properties of 6 commercial butter colors were studied. The principal coloring matter of Hansen's Columbian, Wells, Richardson and Co.'s Improved, and Perry's Concentrated butter colors was found to be coal-tar products, and that of Hansen's Danish, Thatcher's Orange, and Annattoine was found to be annatto. The first 5 samples were solutions of the coloring matter in oil; the 6th was a finely divided powder. "No attempt was made to do more than find the principal coloring matter in each sample." The coal-tar colors found in the first 3 samples were found to be two in number—*anilin yellow* (*amidoazobenzin*) and *butter yellow*, closely resembling *methyl orange*.

Doses of 25 and 42 drops of Perry's Concentrated butter color were taken by persons without any ill effects. Doses of 2 gr. of *anilin yellow* and of *methyl orange* produced no unpleasant results. Both of the coloring matters were rapidly excreted in the urine. The physical and chemical tests of Wells, Richardson and Co.'s Improved, and Hansen's Columbian butter colors gave identical results. The physiological action of the two was very similar. Doses of 24 to 32 drops produced headache, loss of appetite, nausea, vomiting, and nervous depression, the intensity of the symptoms varying according to the amount taken.

**The action of rennet**, G. LÖRCHER (*Arch. Physiol. [Pflüger]*, 69, No. 3-1, pp. 141-198).—This article details over 50 experiments on the effect of various chemicals, heat, etc., on the action of rennet in curdling milk; studies on rennet zymogen, etc. The author describes the method of preparing the rennet. Where a very active rennet is desired which is not to be kept for any length of time the acid extract is recommended; but for securing a preparation which will keep and which is designed for investigating the zymogen and the enzyme the glycerin extract is preferred. The effect of a long list of chemicals on the curdling of milk by rennet was studied. These included various salts of potassium and sodium, of the alkaline earths, magnesium, aluminum, zinc, cadmium, and barium. Special experiments were made on the effect of common salt. The effect of solutions of various strengths were studied. The literature of this part of the subject is reviewed and the method of work is given.

The salts of potash and soda nearly all had a greater or less disadvantageous effect on the curdling. Sodium hydrate and potassium hydrate had the greatest effect in retarding the curdling, followed by sodium fluorid and potassium oxalate. The retarding action of the carbonates and bicarbonates was somewhat weaker, and these were followed in order by the sulphates and nitrates, which in quite concentrated solutions did not prevent curdling. Lithium chlorid formed an exception, in that in certain concentrations it slightly accelerated the action of rennet. The salts of sodium and potassium in like molecular quantities differed very little in their action on rennet, although in concentrated solutions the potash salts were on the average somewhat the more injurious.

Unlike the salts of the alkali metals the salts of the alkaline earths materially accelerated the rennet curdling. Calcium hydrate and barium hydrate were disadvantageous on account of their alkaline action. The various salts of magnesium, zinc, cadmium, and aluminum in medium concentration were on the whole more frequently beneficial than injurious.

A number of experiments on the effect of common salt used in different proportions in normal and watered milk showed that salt accelerated the curdling in milk strongly diluted with water, although this action was not uniform in the case of different milks diluted to the same extent. The reason for this the author was unable to determine, although it is suggested as probably due to the difference in the salt content of different samples of milk.

In further experiments on the specific effect of calcium chlorid it was found that the curdling was more rapid and the amount of curd formed during the process of rennet curdling was greater the more lime salt the milk contained and the longer it was allowed to act. Both the transformation of the casein by rennet and the union of the paracasein and lime salts require time; and both of these processes go on more rapidly when they take place simultaneously than separately. The experiments did not determine whether the accelerating action of the lime salts was due alone to the precipitation of the paracasein or whether the lime salts accelerated the transformation of the casein by rennet.

Alkali was found to decompose rennet, and decomposition was more rapid and complete the weaker the rennet solution, the more concentrated the alkali, and the longer it acted. The action of acids on rennet was found to be very similar to that of alkali.

As to the effect of temperature it was found that boiled milk curdled more slowly than raw milk; that an acid reaction increased the resistance of rennet to temperature; that solutions of rennet in glycerin were more resistant to a high temperature than aqueous solutions; that rennet curdling is possible between  $10^{\circ}$  and  $50$  to  $60^{\circ}$ ; and that the rennet enzym in medium concentration is destroyed by heating for 10 min-

utes at 60 to 70° C. Finally, it was found that the rennet of frogs was more active at low temperatures than that of man and calves, although at medium temperatures the latter was the more active.

Concerning the relation between the amount of rennet and the time of curdling it was found that these were proportional only within narrow limits, and that, in general, where large quantities of rennet were used the curdling took place more slowly.

The remainder of the experiments related to studies of rennet zymogen, the amount of rennet in the lining of the stomach under different conditions of nutrition, etc. The results are briefly summed up as follows: The content of rennet enzym in the lining of the stomach is very low in both fasting and digesting animals, but is greater in the case of fasting animals. The content of zymogen is considerable, whether the animal is fasting or digesting food.

**Tainted or defective milks, their cause and methods of prevention, H. L. RUSSELL** (*Wisconsin Sta. Bul. 62, pp. 27, figs. 10*).—In this bulletin the author treats in a popular manner the established facts relating to the cause, nature, and prevention of taints. Taints are divided under two general heads—(1) those produced by living organisms, and (2) those due to the absorption of odors or to the derangement of the normal functions of the animal. By way of introduction, the bacteria of milk, the manner in which they get into milk, effect of temperature on their growth, etc., are discussed in a quite general way. Following this various specific fermentations, causing taints in milk and cheese, are described and illustrated. The direct absorption of taints before and after milking, the discrimination between directly absorbed and biogenic taints, treatment of tainted milk, and the method of eliminating taints are treated in logical order. In conclusion, a valuable list of suggestions is given for producers in regard to the care of milk, covering the care of animals, milking, storage and transportation of milk, and care of utensils.

“In caring for milk it should be remembered that two things are necessary:

“(1) To prevent the absorption of any foul odors.

“(2) To prevent the development of living organisms in the milk that are able to form foul substances that taint the same.

“The first can be accomplished by keeping taint-producing feeds from the cow and by keeping the milk in a place that is free from all undesirable odors. The second result can be attained by thorough cleanliness combined with a low temperature.”

**Government aid to dairying in Denmark, B. BÖGGILD** (*Ugeskr. Laudm., 42 (1897), Nos. 28, pp. 361-364; 29, pp. 376-379*).

**Milk: Its decomposition and preservation, R. R. DINWIDDIE** (*Arkansas Sta. Rpt. 1897, pp. 49-77, pls. 3, figs. 3*).—A reprint of Bulletin 45 of the station (E. S. R., 9, p. 689).

**Bacteria and the dairy, C. E. MARSHALL** (*Michigan Sta. Bul. 146, pp. 19*).—A popular bulletin on this subject, treating of the fermentations of milk, means of infection, use of pure cultures, etc.

**Annual report of the office for chemical examinations in Breslau** (*Abs. in Milch Ztg., 26 (1897), No. 35, pp. 558-560*).—During the year 340 samples of butter were examined, of which 34, or 9 per cent, were regarded as suspicious, usually on account of high water content, high salt content, or being in a spoiled condition. The standard fixed for the city since 1896 has been not over 3 per cent of salt, 15 per cent of water, and in doubtful cases at least 80 per cent of fat. It is believed that normal butter should not contain more than 15 per cent of water. The analyses are given of a number of samples of butter with a high salt content, with a high water con-

tent, or suspected of being in a spoiled condition or adulterated with oleomargarin. In a number of cases the salt content was over 8 per cent and in one instance it was 13.5 per cent. Four cases are given in which the water content was over 30 per cent, being 18.5 per cent in one case.

Tests were made of the Gerber milk test for determining the fat content of butter. It was found that the test was fairly accurate, but could hardly be relied on for more than a preliminary test, and the determination of water in a calibrated tube was preferred, together with the test of the behavior of the sample on melting, *i. e.*, the so-called Bischoff's test (*E. S. R.*, 8, p. 25).

**Report of the Nuremberg municipal laboratory for the examination of foods and condiments during 1896** (*Milch Ztg.*, 26 (1897), No. 41, p. 653).—The part of the report cited has to do with the control of milk and butter. In 11 cases the milk appeared to be skimmed, but the low fat content was found to be due to the fact that the milk from the first part of the milking was placed upon the market, while that from the last part was used for feeding calves. The author emphasizes the necessity for a legal definition of whole milk.

The average of the analyses of 333 samples of normal milk is given as follows: Specific gravity 1.0319, total solids 12.91 per cent, and fat 3.90 per cent. The composition of 32 samples of butter examined during the year is given as follows:

*Composition of butter in Nuremberg.*

	Degree of acidity of butter.	Degree of acidity of butter fat.	Water content.	Fat content.	Köttstorfer saponification number.
			<i>Per cent.</i>	<i>Per cent.</i>	
Maximum.....	11.80	12.30	21.74	86.50	228.2
Minimum.....	3.60	1.40	12.00	76.70	220.2
Average.....	5.70	4.42	15.54	83.66	225.8

**Report of the hygienic institute on food control in Hamburg to 1896, inclusive**, DUNBAR and FARNSTEINER (*Milch Ztg.*, 26 (1897), No. 35, pp. 552-554).—The parts of the report noted have to do with the control of dairy products, especially milk and butter. The average water content found for 292 samples of creamery butter was 13 per cent, and 91 per cent of the samples contained less than 16 per cent of water. Of 819 samples of tub butter or butter of unknown origin, 348 samples contained 16 per cent or less of water, 138 contained from 16 to 19 per cent, 319 contained from 19 to 28 per cent, and 14 contained over 28 per cent of water.

The question is discussed of the allowable amount of water in tub butter. In Hamburg the limits fixed are 16 per cent of water for creamery butter and up to 19 per cent for tub butter. It is stated that in tub butter containing a high percentage of water, oleomargarin, peanut oil, etc., are added to the butter to prevent the water from separating out on keeping. Borax and "starch sirup" (glucose) are also said to be frequently added to butter to hold water which has been worked into it.

**Milk and dairy inspection**, M. P. RAVENEL (*Pennsylvania Dept. Agr. Rpt. 1896*, pp. 447-457).—The danger of transmission of disease through milk is pointed out by numerous citations, and an appeal is made for dairy inspection.

VETERINARY SCIENCE AND PRACTICE.

**The contest against bovine tuberculosis**, B. BANG (*Ugeskr. Landm.*, 43 (1897), Nos. 41, pp. 485-489; 45, pp. 599-604).—An address delivered at the Agricultural Congress held in Stockholm in July, 1897.

Since 1893 extensive trials have been conducted in Denmark by the author for the prevention of tuberculosis by means of the tuberculin test, isolation of healthy and of diseased animals, and feeding of calves with boiled milk, etc. The summary tables given show that 5,733 herds have been tested, containing in all 158,991 animals, or about 5 per cent of the total number of cattle in the country. Twelve hundred and seventy-four herds, or 22 per cent, were found healthy at the first inoculation. Of the total number of animals tested, 48,955, or 31 per cent, reacted. The author finds, however, that the percentage of reacting animals is on the decrease, being, in 1894, 40 per cent; in 1895, 38.7 per cent; and in 1896-97, 31 per cent. The extent of tuberculosis among animals of different ages was found to be as follows:

*Tuberculosis in animals of different ages.*

Age.	Healthy.	Reacting.	Per cent reacting.
Under one-half year .....	22, 109	2, 989	11. 9
About one year .....	28, 178	8, 328	22. 8
About two years .....	15, 976	7, 862	33. 0
Full-grown cattle .....	43, 773	29, 776	40. 5

The measures recommended by the author for the eradication of bovine tuberculosis are summarized below:

- “(1) To ascertain the actual distribution of the disease in the herd.
- “(2) To isolate the diseased from the healthy animals so far as possible, and to thoroughly disinfect the stable where the latter are to be placed.
- “(3) To see to it that the healthy calves are not infected through the food (milk).
- “(4) Remove the plainly tuberculous (far-gone cases) from the herd by selling them for meat as soon as possible.
- “(5) If the number of reacting animals is small, it may be best to remove all of them from the herd. Otherwise they are kept so long as they do not show clinical signs of tuberculosis, and used as milch cows as heretofore. They must, however, be watched closely to observe in time in case tuberculosis of the udder should develop or the tuberculosis on the whole should progress appreciably.
- “(6) The calves of reacting animals, unless these show symptoms of advanced tuberculosis, are also kept, but they are immediately after calving removed from the infected stable to a calf barn, or if there is no such building to the healthy division. The calves are allowed the colostrum milk of the dam the first day, but from the second day on only boiled milk (or milk heated to 85° C.) or otherwise milk of perfectly healthy cows.”

—F. W. WOLL.

**The contest against tuberculosis of cattle, O. VOGES** (*Der Kampf gegen die Tuberculose des Rindviehs, 1897, pp. 82*).—This is a lengthy popular essay on the subject of tuberculosis in which the difficulties of dealing with it are brought out and the legal enforcement of a plan of extermination similar to that of Bang in Denmark advocated for the German Empire. The enforcement of such a plan for 5 years it is thought would very effectually eradicate the disease. The use of tuberculin is very highly commended. The difficulties that arise in its use, such as have been learned from its use in America, are not brought out.

Referring to the subject of inheritance of tuberculous, it is shown that so far as anatomical evidence is concerned, of 1,000,000 calves butchered in Munich only 5 were evidently born with tuberculous. Of 170,000 calves killed at Berlin during the years 1885 to 1887 only 13 were tuberculous, while of 230,000 killed in Ogsburg between 1873 and 1886, inclusive, only 9 were found diseased; while of 370,000 killed in Prussia during 1888 and 1889 only 73 were found to be tuberculous. This amounts to 1 case of inherited tuberculous in 196,666 calves. Bang's tuberculin experiments, the results of which indicate a much larger percentage of inherited tuberculous than is here reported, are also noted.

The positive inability to definitely determine whether an animal is tuberculous, without dividing the whole animal up into sections of microscopic thinness and making a microscopic study of the same, is pointed out.

**Hog cholera and swine plague**, W. B. NILES (*Iowa Sta. Bul. 35, pp. 769-780*).—A popular article on these diseases, with suggestions for their prevention, etc. Attention is called to the difficulty of diagnosing. The author is of opinion that when a large number of swine die in a neighborhood they are attacked by either the one or the other of the 2 diseases.

The contagious character of the diseases, means of spreading, etc., are discussed, and the popular notion that they are due to feeding new corn is controverted. Keeping an animal in vigorous health by the observance of hygienic rules will render it to a certain extent less liable to any disease, but it will not render it immune against these swine epizootics. Bad sanitation the author considers to be of greater assistance in spreading the disease than all other causes. As to the remedies, the author asserts that the reputation gained by cholera compounds has been gained when the animal would have recovered without any treatment. "A purgative at the outset of the disease, followed by some antiseptic like carbolic acid or hyposulphite of soda, will give as good results as anything."

Preventive measures are more important. Objection is raised to the inoculation method of Billings et al., that the disease is apt to be spread as well as cured. The serum method it is thought will be of much service if it proves practicable, but the method of mixing the serum with the virus, as has been done in some recent experiments, seems to be open to the same objection as the older methods of inoculation.

The author is of the opinion that much more could be done by the swine owners themselves. The most essential measure is the exclusion of all sources of contagion. To accomplish this all swine bought for feeding or breeding purposes should be quarantined for at least 30 days before being placed with the herd, and the water supply carefully looked after, that from deep wells being preferable.

"After the disease appears something can be accomplished by separating the herd into small bunches kept some distance apart, by cremating the dead, and by disinfecting the yards and pens by the free use of lime or crude carbolic acid. If the farm is restocked with swine, new yards should be provided. . . .

"If every swine raiser would remember the main facts, viz, that the disease is communicable, occurring only as the result of the presence of the cholera or swine plague germ; that the sick or exposed hog is the usual carrier of the virus, that the disease is incurable, and should then do the best he can to exercise the necessary precautions to prevent disease reaching his premises, the great annual loss would be very greatly reduced."

**Diseases of sheep observed in Iowa**, W. B. NILES (*Iowa Sta. Bul.* 35, pp. 781-819, figs. 10).—The location of diseased flocks in the State was determined by means of a circular letter addressed to persons engaged in the sheep industry. Most of the diseases observed were found to be largely due to parasites. The author describes more or less in detail in a popular manner, giving appropriate remedies, the following: The sheep tick (*Melophagus ovinus*), the scab mite (*Psoroptes communis*), which seems not to be widespread and at present confined to a few farms; the sheep gadfly or bot fly (*Æstrus oris*), the stomach worm (*Strongylus contortus*), which in 1896 caused more loss than all other sheep affections combined and seems to be rapidly becoming more widely disseminated over the State; *Æsophagostoma columbianum*, which is very common in Iowa; *Tenia caninus*; *T. expansa*, which is very prevalent in Iowa; *Trichocephalus affinis*, which is somewhat common; lung worms; foot rot; actinomycosis; infectious abortion, and louping ill.

Diseases supposed to be the louping ill were reported, but careful consideration leads the author to believe that there was a mistake in identification and that louping ill does not occur in the State.

**Cases of poisoning from rape-seed cakes**, B. BANG (*Ugeskr. Laendm.*, 43 (1897), Nos. 44, pp. 589-591; 45, pp. 604, 605).—About 20 cows of a herd of 77 head were made sick by feeding a lot of French rape-seed cake, and 9 died. Two cows fed experimentally with 3 and 4 lbs., respectively, of the meal soaked in water had colic and died within 12 hours. The effect was attributed to the presence of large quantities of mustard oil in the oil cake, 0.56 per cent being found. A similar poisoning case is on record from Belgium. Fed in small quantities, not to exceed 2 lbs. per head daily, the cake did not seem to produce any injurious effect.—F. W. WOLL.

**Animal parasites of Nebraska**, H. B. WARD (*Nebraska State Bd. Agr. Rpt.* 1896, pp. 173-189, figs. 12).—*Statistical studies of Nebraska parasites* (pp. 173-180).—Twenty dogs and an equal number of cats were examined and the former found to be parasitized to the extent of 75 per cent. Of these 15 per cent were infected with 1 species, 40 per cent with 2, and 20 per cent with 3. Twenty per cent were only slightly and 20 per cent were badly infected. The species of parasites found and the number of animals infected by them were *Tania marginata*, 1;

*T. serrata*, 9; *T. serialis*, 1; *Dipylidium caninum*, 13; *Ascaris mystax*, 4; *Uncinaria trigonocephala*, 2; and *Echinorhynchus* sp. (?), 1. These results are compared with some obtained in other parts of the world, and American dogs shown to be very badly affected. This is due to the large number of *Tenia serrata* and *Dipylidium caninum* harbored. These two forms are relatively much more abundant here than in any other country. The parasites found most abundantly in the dog come from the rabbit.

Of the 20 cats examined all but one were infected with from 1 to 4 species of parasites. Thirteen were only slightly and 3 were badly infected; 5 contained *T. crassicollis*, 3 *Dipylidium caninum*, 6 *Distoma felineum*, 14 *Ascaris mystax*, and 5 *Uncinaria trigonocephala*.

A comparison of the tables given by the author shows that the cats were not so badly affected as the dogs. The largest total number of parasites collected from any cat was less than 60, while 4 dogs were found which contained from 200 to 500 each. The Distomid was found in large numbers, and, on account of the difficulty of being sure in cases apparently free from this parasite it may have been much more abundant than the figures show.

Besides the dogs and cats, 162 chickens, 9 ducks, 56 turkeys, and 1 goose were examined. Sixty chickens, 2 turkeys, and the goose were found to be affected. Cestodes were found in 14 per cent of the chickens and 4 per cent of the turkeys; nematodes in 26 per cent of the chickens and in the goose.

*Parasites new to Nebraska* (pp. 180-189).—In this section there is given a general description of *Tenia confusa*, a new human tapeworm, of which a detailed description is in preparation. In some respects this parasite appears to be intermediate between the pork tapeworm, *T. solium*, and the beef tapeworm, *T. saginata*. It has the slender appearance and delicate structure of the former, while its segments are larger than those of the latter. So far 2 specimens have been found, only 1 of which had the head in position. The other specimen measured some 500 cm. in length.

Another species, *T. serialis*, found in the small intestine of the dog and listed in the former report as *T. cœurus*, later studies show to be the species described by Railliet in 1863.

The rest of the report is devoted to the round worms (*Heterakis perspicillum*), found in chickens, *Uncinaria trigonocephala*, and *Sclerostoma equinum*, taken from a horse near Lincoln.

**The bacterium of the foot and mouth disease**, A. STUTZER and R. HARTLEB (*Arch. Hyg.*, 1897, No. 4, pp. 372-404).—The growth upon media of the specific organism causing this disease is described in more or less detail, together with inoculation experiments on mice and guinea pigs. It is shown that the organism varies its form according to the media in which it is grown. Sometimes it appears as oval rods scarcely  $1\frac{1}{2}$  times as long as it is broad. Under some conditions it appears as a coccus, a diplococcus, or streptococcus, while under other conditions it may appear as a staphylococcus, or even a filiform fungus. The author notes that former investigators

have not sufficiently recognized the very considerable power of change of form that the organism possesses. The essential difficulty, which needs further study, is not the morphology but the physiology of the organism.

**Circulars of the live stock sanitary board** (*Pennsylvania Dept. Agr. Rpt. 1896*, pp. 432-447).—Four circulars on directions for inspecting herds for tuberculosis, for disinfecting stables, and on precautions and measures to be observed to prevent the re-introduction and redevelopment of tuberculosis in inspected herds and questions and popular answers relating to tuberculosis in cattle.

**Report on rabies in central Pennsylvania**, U. G. HOUCK (*Pennsylvania Dept. Agr. Rpt. 1896*, pp. 458-465).—A more or less detailed account is given of attacks of rabies, in several cases embracing dogs, cows, horses, and man.

**A summary of clinical bacteriology**, R. WURTZ (*Précis de Bacteriologie Clinique. Paris: Masson et Cie., pp. 544, figs. 57*).—This is a laboratory compendium for the worker in clinical bacteriology. A description is given of material and of local manifestations of infectious diseases, their bacteriology and the general bacteriology of microbic diseases discussed.

**A revision of the adult tapeworms of hares and rabbits**, C. W. STILES (*Proc. U. S. Nat. Mus., 19 (1896) pp. 145-235, pls. 26; abs. in Zool. Centbl., 4 (1897), No. 18-19, pp. 617-619*).—Analytical keys and specific descriptions are given. The author is disposed to recommend that type specimens should be deposited in the U. S. National Museum and that they should be preserved as balsam mounts. The known leporine cestodes belong to 5 genera: Anoplocephala, Andrya, Bertia, Cittotænia, and Davinea. The first and the last two are thought to be perfectly valid. The second and third are thought to be of uncertain validity, although the author is of the impression that they will finally prove to be valid. In the future more attention must be paid to minute anatomical details in determining genera and species and the principle of homoplasmy must be recognized.

**Embedding tissue without hardening in alcohol**, A. DOLLKEN (*Ztsch. Nuki., 14 (1897), pp. 32-35; abst. in Jour. Roy. Micros. Soc. [London], 1897, No. 5, pp. 448, 449*).—Where animal or vegetable tissues contain substances soluble in alcohol or ether and thin sections are needed, they may be fixed in chrome-osmium acetic acid and in picric acid solution, after which they may be embedded in gum and exposed for 24 hours to the action of acetone vapor at ordinary temperature. Thinner sections than those obtainable by this method may be obtained according to the following method: Small pieces of tissue fixed in 10 to 20 per cent formalin are placed in a capsule to which some resorcin and glycerin are added. The mass stiffens in a short time and is capable of being sectioned in a few hours. It may be fixed to the block of the microtome with water glass or syndetikon, and should be sectioned at once, as it soon becomes very hard.

The author also obtained good results by embedding in soap made as follows: Castor oil or stearic acid, with 20 to 30 per cent of caustic soda, is boiled for a while, and, after cooling the alkali, removed by pressure, dilution, or by frequently dissolving the soap. A piece of tissue about 1 cc. high is transferred from the formalin to a 3 to 5 per cent solution of soap made with distilled water, and allowed to remain in it 36 to 72 hours in a covered vessel. Solidification is brought about by evaporation or by means of powdered Glauber salts. The block is then fixed to the microtome with water glass and the sections are cut dry. They roll somewhat, but may be straightened in water. The soap must be washed out before staining. The addition of 5 cc. of glycerin and of alcohol to each 55 cc. of the soap solution greatly aids in orientation.

## AGRICULTURAL ENGINEERING.

**Influence of width of tire on draft of wagon, H. J. WATERS** (*Missouri Sta. Bul. 39, pp. 165-206, figs. 11*).—Experiments on this subject are reported in detail, with numerous figures and diagrams. The results are summarized as follows:

“Numerous tests of the draft of wide and narrow tired wagons have been made at this station during the past two years on macadam, gravel, and dirt roads, in all conditions, and on meadows, pastures, and plowed fields, both wet and dry. The draft has been determined by means of a self-recording dynamometer. The net load was in every trial the same, viz, 2,000 lbs. Contrary to public expectation, in a large majority of cases the draft was materially less when tires 6 in. in width were used than when the tests were made with tires of standard width—1½ in. The following is a summary of the results:

“(1) On macadam street, as an average of the 2 trials made, a load of 2,518 lbs. could have been hauled on the broad tires with the same draft that a load of 2,000 lbs. required on the narrow tires.

“(2) Gravel road. In all conditions of the gravel road, except wet and sloppy on top, the draft of the broad-tired wagon was very much less than that of the narrow-tired wagon. Averaging the 6 trials, a load of 2,482 lbs. could be hauled on the broad tires with the same draft required for a load of 2,000 lbs. on the narrow tires.

“(3) Dirt roads. (a) When dry, hard, and free from ruts and dust 2,530 lbs. could have been hauled on the broad tires with the same draft required for 2,000 lbs. on the narrow tires. (b) When the surface was covered with 2 or 3 in. of very dry, loose dust, the results were unfavorable to the broad tire. The dust on the road in each of these trials was unusually deep. (c) On clay road, muddy and sticky on the surface and firm underneath, the results were uniformly unfavorable to the broad tires. (d) On clay road, with mud deep and drying on top or dry on top and spongy underneath, a large number of tests showed uniformly favorable to the broad tire. The difference amounted to from 52 to 61 per cent, or about 3,200 lbs. could have been hauled on the broad tires with the same draft required to draw 2,000 lbs. on the narrow tires. In this condition of road the broad tires show to their greatest advantage. As the road dries and becomes firmer, the difference between the draft of the broad and narrow tires gradually diminishes until it reaches about 25 to 30 per cent on dry, hard, smooth dirt, gravel, or macadam road, in favor of the broad tire. On the other hand, as the mud becomes softer and deeper, the difference between the draft of the 2 types of wagons rapidly diminishes until the condition is reached when the mud adheres to both sets of wheels; here the advantage of the broad tire ceases entirely, and the narrow tires pull materially lighter. (e) Clay road, surface dry, with deep ruts cut by the narrow tires in the ordinary use of the road. In every trial the first run of the broad tire over the narrow-tire ruts has shown a material increased draft when compared with that of the narrow tire run in its own rut. The second run of the broad tires in the same track, where the rut is not deep, completely eliminated this disadvantage, and showed a lighter draft for the broad tire than the narrow tire showed in the first run. Where the ruts were 8 in. deep, with rigid walls, 3 runs of the broad tire in its own track over the ruts were required to eliminate the disadvantage. Three runs of the broad tire over this track have in all cases been sufficient, however, to so improve the road surface that both the broad and narrow-tired wagons passed over this road with less draft than the narrow tires did in the original ruts. In addition to the saving of draft, the road was made very much more comfortable and pleasant for the users of light vehicles and pleasure carriages by the few runs of the 6-in. tire. Summing up all the tests on dirt roads, it appears that there are but three conditions on which the broad tires draw heavier than the narrow tires, viz: (1) When the road is sloppy, muddy, or

sticky on the surface, and firm or hard underneath. (2) When the surface is covered with a very deep loose dust and hard underneath. (3) When the mud is very deep and so sticky that it adheres to the wheels of both kinds of wagons. It appears that the dust must be extraordinarily deep to show a higher draft for the broad than for the narrow tires. The three conditions just named, therefore, are somewhat unusual and of comparatively short duration. Through a majority of days in the year and at times when the dirt roads are most used and when their use is most imperative, the broad-tired wagons pull materially lighter than the narrow-tired wagons.

"(4) A large number of tests on meadows, pastures, stubble land, corn ground, and plowed ground in every condition, from dry, hard, and firm to very wet and soft, show without a single exception a large difference in draft in favor of the broad tires. This difference ranged from 17 to 120 per cent.

"(5) It appears that 6 in. is the best width of tire for a combination farm and road wagon; and that both axles should be the same length, so that the front and hind wheels will run in the same track."

**Experiment farm barn well suited for animal comforts, F. E. EMERY** (*North Carolina Sta. Bul. 143, pp. 188-190, fig. 1*).—The experiment station barn, with its attached shed, is described, and observations on the temperature inside and outside of the barn during 1895 and 1896 are reported. The records show a wider range of temperature outside than inside the stable, "but when comparisons are made of the mean monthly temperatures the greater range is found to have averaged much nearer the average stable record than might have been expected. The stable averages warmer for the winter half of the year and cooler during the summer half."

### STATISTICS—MISCELLANEOUS.

**Tenth Annual Report of Arkansas Station, 1897** (*Arkansas Sta. Rpt. 1897, pp. 7, Append. pp. 140*).—Organization list, brief report by the director on the bulletins issued and the general work of the year, and a financial statement for the fiscal year ending June 30, 1897. The appendix is made up of reprints of Bulletins 44-48 of the station.

**Ninth Annual Report of New York Cornell Station, 1896** (*New York Cornell Sta. Rpt. 1896, pp. 3-34, Append. pp. 35-622*).—Brief reports by the director and heads of departments on the work of the year, subject list of bulletins published since the organization of the station and text of the Federal law under which the station was organized. The appendix contains reprints of Bulletins 106-123 of the station, indexes of illustrations and text, and a detailed statement of receipts and expenditures of the station for the fiscal year ending June 30, 1896.

**Tenth Annual Report of New York Cornell Station, 1897** (*New York Cornell Sta. Rpt. 1897, pp. XXI, maps 2; Append. I, pp. 352; II, pp. 353-374; III, pp. 67, figs. 46*).—The report proper consists of a review of the work of the station by the director and heads of the department for the six months ending June 30, 1897. Appendix I is made up of reprints of Bulletins 124-136 of the Station and Circulars 5 and 6, which give suggestions concerning cooperative tillage experiments with potatoes, sugar beets, and fertilizers. Appendix II contains a detailed statement of the receipts and expenditures of the station for the six months ending June 30, 1897, and an index of illustrations and text of the above-noted bulletins. Appendix III is a reprint of Teachers' Leaflets on Nature Study 1-7, dealing with the following subjects, respectively: How a squash plant gets out of the seed, how a candle burns, four apple twigs, a child's garden, some tent makers, what is nature study, and hints on making collections of insects.

**Reports of director and treasurer of Rhode Island Station, 1896** (*Rhode Island Sta. Rpt. 1896, pp. 153-172, 370-380, I-XIX, map 1*).—Report of the treasurer for the fiscal year ending June 30, 1896, and a detailed review by the director of the

organization and work of the station during the year. Lists of donations, exchanges, and publications of the station since its organization in 1888 are given, together with an index of the report and bulletins of the station for 1896.

**Reports of director and treasurer of West Virginia Station, 1896** (*West Virginia Sta. Rpt. 1896, pp. 4-28*).—Includes an account of the purchase and equipment for station use of a farm of 81 acres; notes on the progress and development of the station and on changes in the station staff; subject list of bulletins published by the station since its organization; a detailed financial statement for the fiscal year ending June 30, 1896; and an account of the origin and present status of farmers' institute work within the State.

**Our foreign trade in agricultural products during the five fiscal years 1893-97**, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Bul. 10, pp. 38*).—A statistical review of the total and the agricultural exports of this country for these years. The total value of the agricultural exports for 1897 was \$689,755,193, a gain of \$115,357,929 over the exports for 1896, and more than \$50,000,000 greater than any of the four preceding years.

**Agricultural imports and exports, 1893-97**, F. H. HITCHCOCK (*U. S. Dept. Agr., Section of Foreign Markets Circ. 20, pp. 15*).—Tabular data reprinted from U. S. Dept. Agr., Section of Foreign Markets Bulletin 10 (see above).

**Agricultural and live stock returns of Colony of Cape of Good Hope for 1896-97** (*Cape Town, 1897, pp. XXI, 15*).—General notes on the climate and agricultural conditions of the different subdivisions of the colony, with tabulated statistical data on the farm crops sown, lost, and harvested; live stock; vintage; fruit trees and vine stocks planted, etc.

**Agricultural and live stock statistics of South Australia, 1896-97** (*Adelaide, 1897, pp. 72*).

**Agricultural statistics for British India for the years 1891-'96** (*Calcutta: Office Supt. Govt. Printing, 1897, pp. 377*).—Tabulated data showing the area and classification; total acreage of crops; live stock; assessment on area and population; extent of tea, coffee, and cinchona cultivation; and estimated area and yield of certain principal crops in each of the provinces and districts of India during the years 1891-'96.

**Annual report by the deputy director of agriculture. Bombay presidency, India, 1897** (*Bombay: Govt. Central Press, 1897, pp. 41*).—An account of the cultural, dairying, and breeding operations conducted on the Government experimental farms at Poona and Surat during the year ending March 31, 1897.

**The division of land in Danish agriculture** (*Ugeskr. Landm., 43 (1897), No. 42, pp. 576, 577*).—Gives statistics of the areas devoted to grain raising, meadows, pastures, truck farming, forests, etc., according to investigations made in 1896.

**Export of oranges, season of 1897**, J. STEPHENSON (*Agr. Gaz. New South Wales, 9 (1898), No. 1, pp. 60-63*).—The shipments which have been made to Great Britain of Australian oranges are discussed and suggestions made for conducting the enterprise in future.

**Proceedings of the tenth annual session of the State Agricultural Society, held at Lafayette, Louisiana, January 22-24, 1896** (*Baton Rouge, La.: Issued by State Bureau Agr., pp. 118*).—This gives the constitution, act of incorporation, and officers of the society, and reprints of a number of papers read before the society on various agricultural topics.

**Teachers' leaflets on nature study** (*New York Cornell Col. Agr. Leaflet No. 8, pp. 69-77, figs. 7*).—A popular discussion on the leaves and acorns of our common oaks.

**Agricultural extension work—A sketch of its origin and progress** (*New York Cornell Sta. Rpt. 1897, pp. 325-333*).—A reprint of Bulletin 137 of the station (E. S. R., 9, p. 699).

**Note filing**, L. C. CORBETT (*West Virginia Sta. Rpt. 1896, pp. 240-244*).—A new form of notebook designed by the author for use in the field and as a permanent record is described.

## NOTES.

---

INDIANA STATION.—J. M. Barrett, assistant chemist of the station, has resigned to become chemist for the Hammond Packing House, Hammond, Indiana.

NEBRASKA UNIVERSITY.—An association was organized March 10, 1898, to be known as the Agricultural Students' Association of the University of Nebraska. The officers are: President, C. E. Brown; vice-president, F. A. Swanson; secretary, Charles W. Melick. The executive council is composed of the Chancellor of the University, Dean Charles E. Bessey, T. L. Lyon, A. E. Davison, A. L. Haecker, and C. L. Brown. The work of the association will be to carry on cooperative experiments under the direction and supervision of the heads of the following departments: Agriculture, horticulture, botany, chemistry, entomology, and veterinary science. The object of the association is to promote the cause of agricultural education by causing the students to continue at home the study and investigation which they have begun at the university.

NEW JERSEY STATION.—The following changes have been made in the board of managers of the station: Rynier J. Wortendyke, of Jersey City, has been appointed, *vice* Edmund H. Davey, resigned, and Elwood Evans, of Haddonfield, *vice* Isaac W. Nicholson, deceased.

OKLAHOMA COLLEGE AND STATION.—The board of regents has been reorganized as follows: President, R. A. Lowry, Stillwater; Gov. C. M. Barnes, Guthrie, *ex officio*; R. J. Edwards, Oklahoma City; W. F. Bort, Kingfisher; John C. Towsley, El Reno; treasurer, Chas. J. Benson, Shawnee.

NECROLOGY.—Aimé Girard born at Paris December 22, 1830, died in the city of his birth April 12, 1898. His life was devoted to the study of agriculture and rural economy, and agricultural progress in France has been largely due to his efforts. He made valuable contributions to the study of flours, bread, fibers, etc., but probably his best known and most valuable investigations were those relating to the improvement of the sugar beet and the potato and their domestic and commercial uses. In 1887 he published *Recherches sur le développement de la betterave à sucre*, which was followed in 1891 by *Recherches sur la culture de la pomme de terre industrielle et fourragère*. His knowledge of general chemistry and agricultural and industrial technology well adapted him for his work at the Conservatoire des Arts et Métiers, with which he has been connected since 1871. He was the first occupant of the chair of agricultural technology, established in 1876, at the Institut Agronomique. In 1882 he became a member of the National Society of Agriculture, and in 1890 he was made secretary of the Society for the Encouragement of National Industries. He was elected a member of the Academy of Sciences in 1894, to fill a vacancy in the section of Rural Economy.

## CONTENTS of Vol. IX, No. 11.

	Page.
Editorial notes: Metabolism experiments in some of their relations to the nutrition of man and domestic animals.....	1001
The value of experiments on the metabolism of matter and energy, C. F. Langworthy .....	1003
Recent work in agricultural science .....	1020
Notes.....	1190

## SUBJECT LIST OF ABSTRACTS.

### CHEMISTRY.

Methods of estimating fat, O. Polimanti .....	1020
The lecithin content of certain plant seeds and oil cakes, E. Schulze.....	1020
A new method for determining crude fiber in foods and feeding stuffs, J. König.	1021
Note on the determination of nitrogen as practiced at the agricultural experi- ment station of Aisne, France .....	1021
The Wagner method of determining citrate-soluble phosphoric acid in Thomas slag, B. Sjollem.....	1022
The valuation of phosphatic fertilizers on the basis of their content of citrate- soluble phosphoric acid, P. Wagner .....	1022
The determination of citrate-soluble phosphoric acid in Thomas slag, O. Böttcher.....	1023
Division of chemistry, A. M. Peter.....	1024

BOTANY.		Page.
Report of the botanist, H. Garman .....		1024
Investigations on the ripening of fleshy fruits, C. Gerber .....		1025
Respiration of plants at low temperatures, E. Ziegenbein .....		1026
The action of alcohol on the germination of fungus spores, P. Lesage .....		1026
FERMENTATION—BACTERIOLOGY.		
The occurrence of alcoholic ferments in nature and their transportation, A. Berlese .....		1028
METEOROLOGY.		
Meteorological observations, 1896-'97, W. B. Alwood .....		1034
Special meteorological features of the year 1895, F. Houdaille .....		1032
The daily measurement of dew in 1895, F. Houdaille .....		1032
Causes of the maximum rates of evaporation in the climate of Montpellier, F. Houdaille .....		1032
Variations in winds in the climate of Montpellier, F. Houdaille .....		1033
Actinometric observations during the year 1895, A. Crova .....		1033
Division of meteorology, V. E. Muney .....		1033
WATER—SOILS.		
Tobacco soils of the United States, M. Whitney .....		1035
The moisture of the soil in 1895 and 1896, F. Houdaille .....		1038
On the improvement of humus soils, J. Dumont .....		1038
On the question of the decomposition of nitrates by bacteria, S. A. Sewerin ..		1040
FERTILIZERS.		
Absorptive powers of litter for ammonium carbonate, N. Passerini .....		1041
Analyses of commercial fertilizers, L. L. Van Slyke .....		1042
Analyses of commercial fertilizers, B. W. Kilgore et al. ....		1044
Analyses of commercial fertilizers, W. C. Stubbs .....		1044
"Natural plant food;" claims made for it and its value, B. W. Kilgore .....		1043
Artificial fertilizers from apatite and similar mineral phosphates, G. E. Broms ..		1042
Fertilizer experiments in Smaalenene, Norway, F. H. Werenskiold .....		1043
FIELD CROPS.		
Second report on potato culture, I. P. Roberts and L. A. Clinton .....		1044
Sugar beets in Michigan in 1897, C. D. Smith and R. C. Kedzie .....		1045
Field experiments with wheat, J. F. Hickman .....		1046
Winter pasture, E. R. Lloyd .....		1048
HORTICULTURE.		
Indoor lettuce culture, W. Stuart .....		1048
Forcing tomatoes—comparison of methods of training and benching, S. A. Beach .....		1051
Third report upon Japanese plums, L. H. Bailey .....		1053
Variety tests with raspberries, blackberries, and dewberries, W. Paddock .....		1052
Strawberries in 1897, W. Paddock .....		1052
Strawberries, L. R. Taft and H. P. Gladden .....		1053
SEEDS—WEEDS.

# EXPERIMENT STATION RECORD.

VOL. IX.

No. 11.

In order to establish the rational feeding of man and the domestic animals on a thoroughly scientific basis it is essential that the income and outgo of both matter and energy should be accurately measured. This has led to the development of what are known as metabolism experiments and the devising of special methods and apparatus for such experiments. A digest of the published accounts of metabolism experiments has recently been issued as a bulletin of this Office.<sup>1</sup> The present number of the Record contains a brief abstract of that bulletin (p. 1073), together with an article by one of its authors showing the relation of metabolism experiments to other investigations regarding the food and nutrition of man and animals. A complete metabolism experiment involves a determination of the income and outgo of the various chemical elements, especially nitrogen, carbon, hydrogen, and oxygen, which make up the substance of the animal body or are connected with its life processes, as well as of the physical factors involved in the income and outgo of energy. A few brief statements regarding the present status of this subject may serve to indicate its importance and show what remains to be done to work out these problems.

In respiration experiments which have been made in the past the income and outgo of nitrogen and carbon have been successfully measured. The determination of hydrogen has, however, been far from satisfactory. This fact, among others, was brought out in the compilation of experiments with man and animals above referred to. The correctness of such determination depends upon the accuracy of the measurements of water in the respiratory products. The usual plan followed has been to analyze only aliquot portions of the respired air. Some difficulty has been experienced in the accurate measurement of the samples and of the total amount of air. Although the greater part of the water can be easily determined, a satisfactory determination of the total amount has been difficult of accomplishment. All these factors render the measurement of hydrogen a difficult matter. In connection with work on the respiration calorimeter the Storrs Experiment Station, in its investigations carried on in cooperation with Wesleyan University and this Department, has devised a method for determining the water in respiratory products with the desired accuracy. Reference has been made to the method in previous publications,<sup>2</sup>

<sup>1</sup> U. S. Dept. Agr., Office of Experiment Stations Bul. 45.

<sup>2</sup> U. S. Dept. Agr., Office of Experiment Stations Bul. 44.

although the results which have been obtained are not yet published in full.

The measurement of the income and outgo of chlorine, phosphorus, sulphur, and other mineral matters can be accomplished without great difficulty, although it involves considerable labor. In order to establish a complete balance of income and outgo of material in addition to the other factors enumerated the measurement of oxygen is necessary. This was attempted by Regnault and Reiset. Their apparatus and methods have been elaborated and improved by Rosenthal at Erlangen. Investigations with this improved apparatus are about to be undertaken in connection with the nutrition investigations of this Department.

The determination of oxygen would be of value in many ways aside from its theoretical importance. For instance, at present it is not possible to judge absolutely of the gain or loss of protein and fat in the body, although these factors may be approximately determined. If, however, the income and outgo of oxygen was measured, in addition to the determinations now made, the gain or loss of protein, fat, carbohydrates, and water could be accurately determined. These and other deductions which would be possible would be of special interest in such subjects as the following: Feeding for fat and lean; relation of food to fattening of animals; feeding for milk; relation of food to muscular work, and, in general, the foundation of the laws of nutrition, the clearing up of numerous points now uncertain, and the establishment of principles still in doubt.

The determination of the income and outgo of energy is fully as important as the income and outgo of material. One of the important factors in such determination is the heat of combustion of the food and excreta. Brief reference is made to this subject on page 1016. Such determination may be conveniently made with a bomb calorimeter. The form devised by Berthelot has been modified by Hempel and by Atwater. For a number of years the Storrs Station, in cooperation with this Department, has devoted considerable attention, with successful results, to the perfection of the bomb calorimeter and the methods of using it. A few Berthelot calorimeters as modified by Atwater are now in use in this country. Several institutions in the United States also possess Mahler calorimeters. The different forms of calorimeters and the methods employed in calorimetric determinations have been described at length in a previous publication of this Office.<sup>1</sup>

The use of the bomb calorimeter renders possible the measurement of the income of energy and the outgo in the urine and feces. The energy liberated in the form of heat has been successfully measured with the respiration calorimeter devised by Atwater and Rosa, and used in the nutrition investigations of this Department and the Storrs Experiment Station. The results have not yet been published.

# THE VALUE OF EXPERIMENTS ON THE METABOLISM OF MATTER AND ENERGY.

C. F. LANGWORTHY, PH. D.,  
*Officer of Experiment Stations.*

## INTRODUCTION.

The ordinary feeding experiment deals only with the amount and character of the food consumed and its apparent effect, as shown by the amount and character of the growth of the animal or the milk produced. Without disparaging these experiments, which aim at securing practical results in a short time, and which have been very useful in many cases, it is believed that the time has come when more attention should be given by our experiment stations to studying the real cause of the results which are shown by gains in weight and the milk yield. Care is taken to analyze the feeding stuffs used in such experiments, and much stress is laid upon the inaccuracies of the methods of determining the separate constituents of the food. The amount of digestible nutrients in the feeding stuffs used is calculated, and it is assumed that when these feeding stuffs are fed in combination they will be digested in the same proportion as when fed singly or with one other material. But in most of the experiments the processes which are going on in the animal are ignored, and thus an important phase of the subject is neglected. We rely upon the scales and deductions from feeding standards to tell us whether the animal is well nourished on a given ration. When a change of rations is made and the animal makes satisfactory gains on the new ration any beneficial result is credited to the particular feeding stuff substituted. We have, however, no knowledge, particularly in an experiment of short duration, that the animal was not slowly starving on the first ration from its failure to assimilate the amount of nutrients which it was assumed it should digest from the mixed ration, for the body weight of the animal is not a sufficiently sensitive factor and is too subject to changes in the proportions of water of the tissues and in the contents of the alimentary tract to be relied upon solely as the index of the physiological effect.

Metabolism experiments furnish the necessary data for drawing the desired deductions, and it is believed that this line of experimenting is within the reach of many of the stations.

The animal requires food for two purposes: (1) to furnish material for the building and repair of tissue (or the formation of milk), and (2) to supply fuel for heat and energy. Food consists of the nutrients,

protein, fat, and carbohydrates, and various mineral salts. In addition to these water is essential, as is also the oxygen from the air. The nutrients are composed of carbon, oxygen, hydrogen, nitrogen, sulphur, phosphorus, potassium, and other elements. Substances composed of these elements undergo numberless changes, synthetical and analytical, in the processes of digestion, assimilation, and respiration. All the manifold changes of matter and energy are covered by the term metabolism. It signifies the transformation of matter and energy in the animal organism. Practically all material which has undergone metabolism (and which is not stored in the body) is excreted in the urine and respiratory products, although the feces contain metabolic products along with undigested residue of the food consumed.

As previously stated, food is required for the building and repair of tissue and as a source of energy. In the young organism growth is the important consideration. The skeletal framework, tissues, organs, and fluids must be formed from materials supplied in the food. The problem of feeding the young animal is entirely different from that of feeding the adult. It has been found that the digestibility of certain foods is more complete by young than by adult animals, and there are other differences equally marked. In this discussion reference is always made to the adult man or animal unless otherwise stated.

*Laws of nutrition.*<sup>1</sup>—Experiments in metabolism in which the income and outgo of matter and energy are determined depend upon certain fundamental facts. From these facts certain theories of nutrition have been deduced. The more important of these facts and theories follow:

(1) All nitrogen is supplied from the food; that is, no nitrogen is taken from the air.

(2) Nitrogen is excreted only in the urine and feces; that is, no nitrogen is excreted in the gaseous excretory products.<sup>2</sup>

(3) When the animal is supplied with sufficient food the amount of nitrogen excreted in the urine is dependent upon and, under ordinary circumstances, readily adjusts itself to the amount consumed; that is, the amount excreted in the urine becomes approximately the same as that consumed. The greater part of the nitrogen excreted in the urine is in the form of urea. Some is excreted as uric acid (in herbivora as hippuric acid), and a small amount as nitrogen of extractives, etc. There are numerous conditions apparently causing the retention of nitrogen in the body. The gains of nitrogen, however, are small in the adult in health and are seldom long continued. The tendency is toward nitrogen equilibrium.

(4) A certain amount of food material, *i. e.*, protein, fat, and carbohydrates, is required for maintenance. Mineral matter is also essential,

---

<sup>1</sup>In the discussion which follows little reference is made to controversial points. The attempt has been made to state theories in accord with the consensus of opinion of the majority of investigators.

<sup>2</sup>The small amount of nitrogen lost in hair, hoofs, etc., or excreted in perspiration and in volatile organic compounds is left out of account.

but little is known regarding the kind and amount necessary. Protein, fat, and carbohydrates all furnish energy, but protein alone furnishes nitrogen. The above statement may be further simplified by saying that a definite amount of nitrogen and energy is essential.

(5) A more abundant ration is required for muscular work, for fattening, and for milk production than for maintenance: that is, gains in weight, milk, and force for muscular power are produced at the expense of nutrients supplied in excess of the amount required for maintenance.

(6) Food supplied in excess of all needs is stored, in part at least, as reserve material. The principal reserve materials, fat and glycogen, contain no nitrogen, but it is reasonably certain that under certain circumstances a small amount of some reserve material containing nitrogen is also stored up.

(7) If no food is supplied or a diet containing no nitrogen is consumed, nitrogen (derived from body tissue) is still excreted in the urine; that is, the animal is living upon its own substance wholly or in part. Under these circumstances the urine and feces contain more nitrogen than the food; that is, the body is losing nitrogen. When the food contains more nitrogen than is needed there is usually, for a time at least, a small gain of nitrogen in the body, *i. e.*, the urine contains less than the food. However, it does not follow that an excess of nitrogen consumed over the amount essential is stored up in the body. As was mentioned above, the body under ordinary circumstances adjusts itself to new conditions and uses up the nitrogen supplied to it, although it is not altogether certain just how this is accomplished. In other words, the body comes into nitrogen equilibrium; that is, the outgo of nitrogen approximates the income. If all disturbing factors could be controlled, it would probably exactly equal the income, but this can not be said with certainty.

If it were not for the fact that the body comes into nitrogen equilibrium with rations containing different amounts of nitrogen, it is evident that it would continue to form muscular tissue, *i. e.*, cell and cell contents, indefinitely on a ration rich in nitrogen; since muscular tissue (including organs and blood) is the portion of the body characterized by nitrogen. Under some conditions of feeding there are undoubtedly small gains in nitrogen, *i. e.*, muscular tissue.<sup>1</sup> But it is a matter of common observation that overfeeding does not produce more lean, though it does produce more fat.

(8) Fat, which is stored as reserve material, is formed from fat and carbohydrates supplied in the food, and doubtless from protein also.

(9) As furnishers of energy the different nutrients may replace each other in approximately the following ratio: Protein : fat : carbohy-

---

<sup>1</sup> How much of the nitrogen thus stored forms a part of the cell tissue, how much belongs to cell contents, and how much is in circulation in fluids in the body is a question in regard to which opinions differ, and the data for judging this matter are at present inadequate.

drates :: 1 : 2.5 : 1; that is (having the requisite amount of nitrogen, used probably for the repair of tissue or for some vital process less understood, or for both), it is theoretically and within certain limits unimportant which of the nutrients supplies the necessary energy. An abundance of carbohydrates and fat will, within limits, make up for a deficiency of protein; that is to say, the body will get on with a small amount of protein provided a correspondingly large amount of nitrogen-free material is supplied. This is often spoken of as the power of carbohydrates and fat to protect protein.

(10) The nutrients of the food combine in the body with the oxygen of the air and undergo combustion, thus liberating energy for the body.

#### METABOLISM OF NITROGEN.

Metabolism experiments of the kind here referred to may be divided into four classes: (1) Those which show the amount of nitrogen (with or without ash constituents) consumed in the food and excreted in the urine and feces; (2) those which also account for the carbon (with or without oxygen and hydrogen), known as respiration experiments; (3) those which in addition to the above factors take account of the energy of the food and excretory products as well as the energy of internal and external muscular work and the heat radiated from the body; and (4) those in which the respiratory quotient is determined, *i. e.*, the ratio of carbon dioxide excreted in the breath to oxygen consumed from the air.

The first line of experimenting is much the simplest, as to both apparatus required and manipulation, and it also affords data which are of much importance not only in judging of the metabolism of protein, but also as to the general condition of the animal. In experiments on the metabolism of nitrogen as ordinarily conducted, the nitrogen in the food, urine, and feces is determined. The urine contains nearly all the metabolized nitrogen excreted from the body. Under ordinary conditions the amount in the feces is small. Apparatus has been devised for the collection of the urine. The collection of the feces is a comparatively simple matter. The nitrogen in the urine and feces may be readily determined by the ordinary methods. The sum of the nitrogen in the urine and feces (representing the outgo) subtracted algebraically from the nitrogen in the food (income) shows whether a gain or loss of nitrogen in the body is taking place, *i. e.*, whether or not nitrogen is being retained in the form of increased tissue, reserve material, etc. If the income is greater than the outgo there is a gain of nitrogen in the body; if it is less than the outgo there is a loss; if it is just equal to the outgo, nitrogen equilibrium has been reached. Comparing the income and outgo is often spoken of as determining the nitrogen balance.

*Nitrogen metabolism in its relation to feeding experiments.*—The feeding experiment as ordinarily made depends upon considerations like those mentioned above (p. 1004). Yet it is doubtless true that few consider

the more technical points in making such experiments. In a feeding experiment, as usually conducted, an animal, or in many cases a lot consisting of several animals, is fed for a longer or shorter period a given ration of known composition. The amount consumed and the gain or loss in weight are recorded. Often the cost of the food eaten and the value of the animal at the beginning and end of the test are also noted, to furnish the means of judging of the economical value of the ration. A feeding test is generally preceded by a preliminary period of arbitrary duration during which the ration to be tested is fed, in order that the body may adjust itself to the new ration and during the test proper may be actually living upon the ration tested and not upon material stored from the previous ration. When different foods are compared, either similar animals or lots of animals are fed the selected rations at the same time and under similar conditions, or the different rations are fed to the same animal or lots in different periods, separated by suitable preliminary periods. The two methods are often combined. If the feces are analyzed the data are obtained for determining the digestibility of the food, since it is assumed that the feces consist of the undigested residue of the food eaten. It goes without saying that the feeding experiment is more valuable when the comparative digestibility of the foods tested is also learned. The fact that digestion experiments have increased in number in recent years shows that the station workers fully appreciate this fact. That the collection and analysis of the urine affords additional data for drawing deductions from feeding tests and permits the deduction of other important facts is not recognized, or if recognized is not carried into practice.

Determining the nitrogen balance in connection with the feeding experiment is useful in the following ways:

It may be very helpful as an indication of the proper length of the preliminary feeding period or the time when the feeding experiment proper may begin, since the existence of nitrogen equilibrium implies that so far as nitrogen is concerned the body is living upon the food eaten.

It is also helpful as showing whether the ration is sufficient for the needs of the animal. If it is insufficient the body will lose nitrogen or carbon or both. In long feeding experiments this loss would almost certainly appear in loss of weight and in poorer condition of the animal. But if the period is short a change in weight is not a sufficient indication of the physiological condition, for change in weight is known to be influenced by different water content of the body and other factors.

The feeding standards commonly followed have been deduced from the best data available at the time they were proposed and in general are in accord with the best practice. In some instances the amount of nitrogen proposed was influenced by the amount consumed from the tissue of a fasting animal as shown by the excretion of nitrogen in the urine, since it was assumed that when living on its own tissue the

body would live most economically. It is, however, not certain that the best combination of nutrients (protein and nitrogen-free material) has been found and is shown by the feeding standards. For instance, if the ration contains a very large quantity of nitrogen and practically all is excreted in the urine and feces it may be fairly considered as wasteful unless it can be shown that the gains made are enough better to offset the cost of such a ration, for nitrogen is without doubt the expensive nutrient. By better gains is meant that the material gained consists of lean rather than fat, or that the fat and lean are better distributed. Muscle, *i. e.*, lean, contains about 23 per cent of protein (nitrogen multiplied by 6.25) and by this factor the amount of lean may be computed approximately from the gain of nitrogen.

The small gains of nitrogen which are observed in many experiments and which may be due to a variety of causes are often found to be counterbalanced by corresponding losses if the period of observation is long continued. In order that there should be a gain of muscular tissue, of importance from the standpoint of feeding animals for profit, there should be a regular and constant gain of nitrogen of considerable amount. It has been claimed that by special methods of feeding it is possible to cause very considerable increase of gains in muscular tissue. The results of experiments which have been conducted on this line are, however, contradictory. It is not improbable that a system of feeding followed from birth may materially affect the body structure of an animal. Until further observations are made definite statements concerning this question are not warranted.

It is undoubtedly true that different methods of feeding influence the way in which fat is accumulated in the body. It has been claimed that if animals are fattened quickly the fat will accumulate in large masses in certain localities, whereas if the fattening period is of long duration and the fat is accumulated slowly it will be distributed throughout the carcass. The best methods of feeding and the most suitable rations for securing well-distributed fat and lean are not known with certainty. The conditions which influence the constant gain of nitrogen (if this is possible) and hence the gain of lean are not well understood. A consideration of the problem of feeding for lean (whether this be understood to mean feeding so as to insure a better distribution of lean and fat in the carcass or a total gain in muscular tissue) affords one of the most useful investigations in connection with feeding experiments.

As previously stated, determining the gain or loss of nitrogen furnishes data for computing the gain or loss of lean. If it were not for variation in water content of the body as well as in the contents of the alimentary canal the gain or loss of fatty tissue would be shown by subtracting the gain or loss of lean from the total gain or loss, since it is assumed that fat is the only nitrogen-free substance gained in any considerable quantity.

To calculate accurately the gain or loss of fat the balance of income and outgo of carbon must also be known. The measurement of this factor necessitates the use of a respiration apparatus. This will be spoken of later. However, a method<sup>1</sup> for calculating the carbon balance from data furnished by experiments in which the food, urine, and feces have been analyzed has been devised and seems applicable in feeding experiments and experiments on the production of milk.

The length of time a feeding experiment should be continued is shown, in part at least, by determining the nitrogen balance. In the ordinary feeding experiment the proper length of time is largely a matter of conjecture or convenience, the object being to continue the test until the effect of the ration is manifested with certainty. When the nitrogen balance is determined and nitrogen equilibrium is reached and maintained the subject is known to be living upon the tested ration, and continuing the period for a longer time is a matter to be determined by the special question under investigation. For instance, in feeding a certain ration to pigs it is often desirable to learn how long the ration may be profitably fed rather than to study the physiological effect of the ration.

Disturbing conditions will be very readily shown by variations in the nitrogen excretion. If the ration is unvarying and nitrogen equilibrium has been reached the excretion of nitrogen in the urine should be practically uniform from day to day. If this is not the case it is certain that there is a disturbing factor. This would often be undetected in the ordinary feeding experiment, and the fact that there is no certain way of recognizing the presence of disturbing factors when the ration is uniform may account for the fact that contradictory results are so often obtained. In other words, the investigator is not certain that the experimental conditions remain uniform or that they are similar in different experiments. Reaching and maintaining nitrogen equilibrium is an indication that the experiment is progressing regularly, with the experimental conditions under control. This is undoubtedly one of the most important applications of this line of work to feeding experiments.

It is often desirable in the feeding experiment to test some other conditions than rations; for instance, the effect of housing in warm barns. If the special condition studied is sufficient to produce any marked physiological effect it is very probable that this would be shown by variations in the nitrogen balance; that is, a change in the physiological condition would produce a change in the cleavage of protein in the body, and hence in the nitrogen excretion in the urine. Thus, if it should appear in the feeding experiment that drinking large quantities of water increased the excretion of nitrogen in the urine—that is, the cleavage of protein in the body—the deduction would be

<sup>1</sup> Landw. Jahrb., 24 (1895), p. 283 (E. S. R., 7, p. 237); 26 (1897), p. 555 (E. S. R., 9, p. 788).

warranted that the amount of water consumed with a ration should be regulated, unless it was believed to be desirable to furnish large amounts of water. If this were done a correspondingly large amount of nitrogen should also be supplied. If it should appear that the amount of water drunk was without effect on the excretion of nitrogen the conclusion would be warranted that there was no reason for regulating the supply of water.

The manurial value of a ration is an important consideration from an economic standpoint, and this can not be known with certainty unless the nitrogen in the urine and feces is determined.

If feeding tests were made with the additional determinations suggested the results obtained by different observers would be more comparable than is now the case. There is so little proof of uniformity in experimental conditions at present that many of the deductions obtained are only of local or transient interest.

*Nitrogen metabolism in its relation to digestion experiments.*—What has been said of the value of experiments in which the balance of income and outgo of nitrogen is determined as a control on the accuracy of feeding experiments applies with equal force to digestion experiments. In the digestion experiment, as ordinarily conducted, the animal is fed for a longer or shorter period a definite ration consisting of a single food or combination of foods. The ration is fed until it is assumed the animal is living on it, and then the feces are collected and analyzed. Sometimes various substances, such as powdered cork, bones, or charcoal are given with the last food consumed before and the first food after the digestion experiment proper. These substances impart either a definite consistency or color to the feces and permit the separation of the feces due to the special food under consideration from the feces due to the preceding and following ration. From the composition of the food and feces the coefficients of digestibility are calculated. Unless the balance of income and outgo of nitrogen is determined the time which should elapse after a given diet is consumed before the feces should be collected for analysis is more or less a matter of conjecture, as in experiments with herbivora the feces can not be marked, for instance, with charcoal, as may be done in experiments with man.

It is not known with certainty that the digestibility of food is influenced by the state of nutrition of the subject. It seems reasonable to assume that digestion would be normal under normal conditions; that is, when the body is in nitrogen equilibrium.

It has been sometimes assumed that the feces consist principally of undigested residue, but investigations—some of them comparatively recent—have shown that this supposition is far from correct, and that a considerable percentage of the nitrogen of the feces is metabolized nitrogen derived from bile and other digestive secretions. As previously stated, the nitrogen assimilated from a given diet is largely

excreted in the the urine, and, futhermore, it is excreted within a comparatively short time. The nitrogen in the food minus the nitrogen in the feces (which is ordinarily assumed to represent the digested nitrogen) is very nearly the same as the amount excreted in the urine. If the nitrogen of metabolic products in the feces is determined and added to the amount in the urine it is probable that, provided the subject is in nitrogen equilibrium, this sum would more truly represent the total amount of digested nitrogen than the values which are obtained by ordinary methods. At any rate, the values so obtained are useful as a check on the results obtained by taking the difference between food and feces as the amount digested.

In digestion experiments with animals little account is taken of the fact that the digestibility of a food is influenced by the foods which are consumed with it. In experiments with men on an absolute milk diet, a considerable quantity of nitrogen may be excreted in the feces, owing probably to the fact that the milk when consumed in quantity coagulates in the stomach and the masses are not sufficiently broken up in their passage through the intestinal tract so that the digestive juices can act upon the whole mass. On the other hand, if bread is consumed with the milk the particles of bread prevent the formation of large masses of casein in the stomach and the material is in better mechanical condition for digestion, and is actually more thoroughly digested; that is, consuming bread with milk increases the digestibility of the milk. Furthermore, in such experiments it is often impracticable to continue a ration consisting of a single food material for any considerable length of time, because unusual conditions may readily be supposed to eventually produce abnormal results. In all such cases a check on the accuracy of the results is even more valuable than in digestion experiments under normal or usual conditions.

As in the case of feeding experiments, determining the nitrogen balance is useful in showing the regularity of progress of digestion experiments, since if the nitrogen balance does not vary from day to day under like experimental conditions it may be assumed that the experimental conditions are under control, and the results of one investigator may be more readily compared with those of another.

*Other experiments in which the nitrogen balance is of use.*—There are many other matters connected with the subject of nutrition besides feeding and digestion experiments which need investigation, and are in line with the work followed at many of the stations, in which a determination of the balance of income and outgo of nitrogen is either essential or useful. A proper understanding of the functions of food and the amount of food requisite for different purposes, including the production of work, necessitates a knowledge of the source of energy in the animal body. While it is recognized that energy is supplied by the food, there are many theories as to which of the nutrients is the real source of energy in the body. It is now generally held that protein,

fat, and carbohydrates all furnish energy for muscular exertion. Nevertheless, certain prominent investigators urge that this energy is furnished mainly if not entirely by protein. The theory has also been advanced that fat and carbohydrates furnish the energy for moderate muscular work even if long continued, but if the labor is severe the energy for it must be supplied by protein. Many investigators have claimed that muscular work increases the excretion of nitrogen; that is, increases the cleavage of protein in the body. The results obtained are, however, contradictory, and the study of the question of the real source of muscular energy and the effect of muscular work on the cleavage of protein is one which may be advantageously pursued.

Closely connected with the points above noted is the question concerning the time which must elapse before the nitrogen of the food consumed is excreted in the urine. The time which must elapse before the undigested residue of a particular diet is excreted in the feces may be actually determined, since, as noted above, it is possible in many cases to identify the feces by giving them a characteristic color or consistency. There is no such simple means applicable to the urine. It is ordinarily assumed that a comparatively short time elapses before the nitrogen of a particular food is excreted in the urine.

To what extent the nitrogen in the urine is derived directly from the food or to what extent the nitrogen consumed must first form a part of the body tissue before being excreted is a subject on which opinions differ. Whether nitrogen, if stored in the body as reserve material, is stored in nitrogenous cells already formed or whether new cells are built is also a matter on which more information is needed. In skillful hands the data for the intelligent discussion of such problems are furnished, at least in part, by the nitrogen balance. In addition to the determination of the nitrogen balance, the ratio of the different nitrogenous constituents in the urine to each other, and the ratio of phosphorus and sulphur compounds to each other and to nitrogen may be advantageously studied, since these ratios have been shown to vary under different experimental conditions and to furnish a means of judging of the physiological processes going on in the body. In connection with all the work mentioned the elaboration of analytical methods is needed.

*Nitrogen metabolism under abnormal or unusual conditions.*—The study of nutrition under abnormal, unusual, or pathological conditions is of great importance, since it is true here, as in other branches of science, that the normal can not be known with certainty without a knowledge of the abnormal. As previously stated, metabolism experiments with fasting animals are of use in determining the amount of protein which is actually required. A considerable number of metabolism experiments have been made, in which the subjects (usually men) were massaged. Massage may perhaps be regarded as a form of involuntary muscular exertion, and, while interesting from other standpoints, such

experiments are also of use in deducing theories concerning muscular exertion. In other experiments baths of various sorts have been given, in many cases of such a nature that the body temperature was raised. Deductions drawn from these experiments have been of importance in discussions concerning many points. Metabolism experiments with subjects affected with diabetes have been of assistance in studying the functions of fat and carbohydrates, and the ways in which these nutrients are used in the body. Aside from the information they furnish concerning the normal organism, experiments on nutrition in different diseases are of value, considered from a medical stand point. In studying the kind and amount of food best suited to diseased subjects and the influence of disease on digestion and assimilation, and other similar problems, the determination of the balance of income and outgo of nitrogen has been of great assistance.

A number of fundamental facts and theories concerning nutrition were mentioned above (p.1004). In nearly every instance the conclusions cited were arrived at by the aid of metabolism experiments in which the balance of income and outgo of nitrogen was determined. The line of experimenting which has led to such valuable results in the past can not but prove useful if continued.

#### METABOLISM OF CARBON.

In the experiments which have been spoken of the balance of income and outgo of nitrogen was the principal factor determined. Many experiments have also been made in which the balance of carbon, with or without hydrogen and oxygen, was determined. These are called respiration experiments, from the fact that the respiratory products are taken into account. Special apparatus is necessary for the collection, measurement, and analysis of the inspired and respired air. This usually includes a respiration chamber in which the subject may remain in comparative comfort for a longer or shorter period. A current of air, sufficient for the needs of the subject, is pumped through the apparatus. In some forms of respiration apparatus, instead of pumping a current of fresh air through the respiration chamber the carbon dioxid produced is removed and fresh oxygen is supplied to take the place of that withdrawn from the air by the subject. The total current is measured and samples of known volume of both the incoming and outgoing air are analyzed. The factors ordinarily determined is carbon dioxid and in some cases water. In experiments with herbivora the methan in the gaseous excretory products is usually determined also, since a considerable quantity of this gas is known to be excreted in the intestinal gases of this class of animals. In these, as in experiments previously mentioned, the food, urine, and feces are analyzed. The usual determinations made are carbon and nitrogen. In some instances oxygen, hydrogen, and mineral matter are also determined.

As the characteristic elements of all foods and the liquid and solid excretory products are nitrogen and carbon, the characteristic element of the gaseous excretory products is carbon. Therefore, if the income and outgo of nitrogen and carbon are determined the data are secured for measuring approximately the total income and outgo of material,<sup>1</sup> since this may be expressed in terms of nitrogen and carbon.

If the amount of carbon consumed in the food is greater than that excreted in the respiratory products, urine, and feces there is a gain of carbon in the organism, and *vice versa*. If carbon is gained it is ordinarily assumed that it is stored in the body in the form of fat, since this is the characteristic carbon compound present in any considerable amount in the body. If the outgo of carbon is greater than the income it is commonly assumed that the food is insufficient and some fat of the body has been utilized. The percentage of carbon in fat is known, and from the gain or loss of carbon the gain or loss of fat can be calculated. As previously stated, the gain or loss of lean can be calculated from the gain or loss of nitrogen, as the percentage of nitrogen in lean meat is also known. These factors, together with the total gain or loss in weight of the subject, furnish data for judging of the physiological effect of a ration and the comparative value of the gains made on different rations.

The source of fat in the animal body is a question which has been much discussed. As already mentioned, the commonly accepted theory is that fat is formed from the excess of fat and carbohydrates consumed in the food. It has been maintained that when an excess of protein is consumed fat may be formed from protein; that is, the protein is broken down in the body into simpler nitrogenous and nitrogen-free substances. While the nitrogen is excreted, some of the carbon is retained and stored in the form of fat. The early experiments which were regarded as proofs of the formation of fat from protein were made with a respiration apparatus. The subject, generally a dog, was fed lean meat, which was assumed to be free from fat and glycogen. All the nitrogen consumed was excreted. Some carbon was retained. The conclusion was therefore drawn that it was retained as fat; that is, that fat had been formed from protein. The discussion of the accuracy of this deduction and the theories based upon it is still going on. The possibility of the formation of fat from protein is rendered probable by experiments of an entirely different nature.<sup>2</sup>

It has been found that muscular work increases the metabolism of carbon; that is, increases the excretion of carbon dioxide in the breath.

---

<sup>1</sup>In this discussion no mention has been made of mineral matter. In many experiments the balance of mineral matter has been determined either in terms of total ash or of chlorine, phosphorus, sulphur, etc. Though the mineral constituents of the food are of undoubted importance, their function, aside from the formation of the skeletal framework of the body, is not definitely understood. They undergo little cleavage in the body, and hence are of practically no value as sources of energy.

<sup>2</sup>N. Zuntz, E. S. R., 7, p. 538.

This is often the case when there is no increased excretion of nitrogen and when the nitrogen of the excretory product does not exceed that of the food. In these cases carbon compounds (fat and carbohydrates) must be concerned in the production of muscular energy. It does not necessarily follow that this is true for all forms of energy or for the production of the total muscular energy of the body. It has also been claimed that when work is severe the amount of nitrogen excreted in the urine is increased, or, in other words, protein is broken down to furnish energy for muscular work. The different theories of the source of energy were briefly mentioned above. More investigations are needed before positive deductions can be drawn.

Since the total income and outgo of matter are measured in respiration experiments, the data are available for discussing the conservation of matter in the animal body. Although this would hardly be questioned to-day, the experimental proof of the law as applied to the animal body is not only a matter of abstract scientific interest, but of fundamental biological importance.

What was said of the importance of studying the balance of nitrogen under abnormal or unusual conditions applies with equal force to the metabolism of carbon and of energy.

#### METABOLISM OF ENERGY.

The previous discussion has been chiefly concerned with only one of the functions of food, namely, supplying the body with material for the building and repair of tissue. Food is also a source of energy. It supplies the body with the necessary heat and energy for internal and external muscular work. The complex compounds consumed in the food possess high potential energy. Before being excreted they are broken down in the body into simpler compounds and part with this energy. The elements unite with the oxygen of the air and undergo combustion in the body.

In ordinary combustion the final products are carbon dioxide, water, and free nitrogen. In the body carbon and hydrogen are also burned to carbon dioxide and water, although the process is not so simple as in the direct oxidation of material in the air. The nitrogen combustion is, however, not so complete, since nitrogen is excreted in the forms of urea and other cleavage products.

It is believed, in accordance with the principle of the conservation of energy, that the amount of potential energy which is transformed into kinetic energy when food is burned in the body is the same as that which would be produced if an equal amount of the same material was burned outside the body. Provided the final products are the same the intermediate steps may be disregarded. Further, in accordance with the principle of maximum work the tendency is toward those changes which result in the greatest evolution of heat or other form of kinetic energy. Accordingly the heats of combustion of the nutrients of food

are taken as equivalent to their potential energy, *i. e.*, their value for the production of heat and muscular work when they are burned in the body, due allowance being made for the imperfect combustion of the nitrogenous compounds. The same principle applies to the reserve materials, principally fat and protein, which the body takes from the food and makes part of its tissue before they are burned.

In determining the balance of income and outgo of energy the income is represented by the potential energy of the food. The factors of outgo are the potential energy of the excretory products, the heat radiated by the body, and the amount of muscular work performed. These factors may all be expressed in terms of heat. The data for the balance are usually expressed in units of heat, *i. e.*, calories. The potential energy of the food and excretory products is determined by combustion in a bomb calorimeter or other suitable apparatus. Many different dynamometers have been devised for determining the amount of external work performed. Internal work (expended in chewing, swallowing, and digesting the food, in the beating of the heart, etc.) can not be measured directly, but it is believed that the energy involved in this internal muscular work leaves the body in the form of heat. Therefore this internal muscular work can be measured by determining the heat given off by the body. This requires a special apparatus called a calorimeter. When it is combined with a respiration apparatus of some sort, as has been done in a few cases, it may be called a respiration calorimeter.

In stating the results of experiments in which the balance of energy is studied it is of advantage to compare the energy of the food available for the body—that is, the net income—with the energy liberated by the body. The gross income of the food is represented by its heat of combustion. The net income is the gross income less the heat of combustion of the undigested residue and metabolic products in the feces and the unoxidized material in the urine.

When the balance of income and outgo of energy is determined, if the income exceeds the outgo, energy is stored in the body. It is assumed that this is stored as potential energy in fat, protein, or other reserve material. If the outgo of energy exceeds the income then some of the material of the body has been broken down to liberate this energy.

Calorimetric experiments have a practical application in comparing the energy available to the body from different foods. Further, calorimetric experiments will afford a means for judging of the accuracy of respiration experiments and show more clearly what becomes of the nutrients of the food, the carbohydrates as well as the fat, protein, and extractives. Another application is in the study of the production of work by draft animals. It is evident that the study of these problems necessitates the measurement and comparison of the work performed on different rations. Such experiments are also essential in studying

the more general applications of the law of the conservation of energy in the animal body. Although there is no reason to doubt this the experimental proof is a matter of great interest and importance.

Experiments on the income and outgo of energy are comparatively recent. They are very technical and necessitate costly and elaborate apparatus. The results which may be obtained, however, are of extreme importance and their application is widespread. The Connecticut Storrs Experiment Station, in cooperation with this Office, is carrying on elaborate investigations on this matter and it is hoped the work will be enlarged.

#### THE RESPIRATORY QUOTIENT.

In the respiratory experiments previously mentioned the total income and outgo of carbon was determined. There is another class of respiration experiments in which the total income and outgo is not the factor under consideration, but rather the amount of carbon dioxid excreted in a given time as compared with the amount of oxygen consumed from the air. This ratio of carbon dioxid to oxygen is called the respiratory quotient and experiments in which it is determined may be conveniently called respiratory quotient experiments. For such work special apparatus is needed. In some cases the subject is confined in a chamber not unlike that of the other form of respiration apparatus and the amount of oxygen consumed and carbon dioxid produced is measured. In other cases a tube is inserted in the trachea of the animal. Through this tube all inspired and respired air must pass. The tube is provided with suitable valves, and the incoming and outgoing air is measured, sampled, and analyzed. This device does not cause any serious inconvenience to the animal experimented with. Horses and dogs used in such experiments have lived in health for many years after the operation was performed. In experiments with man and sometimes with animals a mouthpiece or a mask over the head is worn, which, by an arrangement of valves, permits the measurement of the inspired and respired air.

The respiratory quotient varies markedly under different experimental conditions and is a delicate index of the processes going on in the body.

It has been found that protein, fat, and carbohydrates each give a different respiratory quotient when burned in the body. It is therefore possible to judge of the substances actually burned in the body by variations in the respiratory quotient. Muscular work, either internal or external, affects the respiratory quotient, since it increases the amount of carbon metabolized, and hence the carbon dioxid excreted. From the ratio the amount of work performed can be computed. Thus by changes in the respiratory quotient it is possible to measure the energy expended—for instance, in chewing and digesting different foods. This affords a method for determining the actual value of different foods

for the body. It is obvious that if two foods have the same composition and digestibility, but one requires twice as much energy for mastication and assimilation, it is only half as valuable for the body as the other.

Very little has been done in America in this line of experimenting. While the work is technical, it is a line the stations can follow to advantage. The results already obtained indicate this to be one of the most promising lines of investigation in nutrition.

#### CONCLUSIONS.

From what has been said it is obvious that the discovery of the principles and fundamental laws of nutrition rest largely on experiments in which the balance of income and outgo was determined. Some of the points on which more work along these lines should be done have already been pointed out. Thus, more careful comparisons of different feeding stuffs and their value for the production of milk, growth, and force are needed. The formation of fat and the value of different foods for the production of energy, the source of energy in the animal body, the effect of muscular work on the excretion of nitrogen and carbon, and many other questions suggest themselves as lines of work which the stations can advantageously follow. Experiments in which the balance of nitrogen is the principal factor determined require no special apparatus and are comparatively simple. They are therefore the ones which may be most readily undertaken, and, as shown by the value of the results, are of the utmost importance.

The ordinary feeding experiment, in which the amount and composition of the food is determined or calculated and the gains in weight of the animals are recorded, has been of use and will be of undoubted use in the future, but it is limited in its application. Many of the questions which such experiments undertake to settle could be solved by the intelligent farmer working in connection with the stations, and many others can not be definitely solved without making the experiments more thorough.

Contradictory results which are often obtained might be frequently avoided or explained if more were known of the state of nutrition of the animal experimented upon. Experiments to determine such factors are beyond the farmers, and must be carried on by the stations. If the simpler lines of experimenting are left to practical men, who are competent to carry them out on their own farms with their own animals, the time and energy of the trained station workers may be given to more technical matters, which are nevertheless fundamental and of importance from a practical standpoint.

*Compilation of metabolism experiments.*—In order to work intelligently along these lines the observer must have a knowledge of experimental methods, he must be familiar with the work already done, and be able to draw deductions from the facts observed. Studying the work of

other investigators often suggests further lines of experimenting, and by comparison of different investigations errors may be avoided. The literature of metabolism experiments is extensive. Reports of experiments have been published in various scientific journals in many languages. Many of these publications are not generally accessible. More or less extended compilations of results have been made in the past, but in no case so far as known have the individual experiments been cited in detail. Therefore a compilation<sup>1</sup> has been prepared in this Office of experiments with man and animals in which the balance of income and outgo of matter and energy was determined. Some 2,300 experiments with man and about 1,400 experiments with animals have been collected. In a large number the balance of nitrogen with or without mineral matter was the factor determined. In a comparatively large number the balance of carbon, with or without hydrogen and oxygen, was also determined. A still smaller number were calorimetric experiments in which determinations of energy were made. The attempt was not made to include the respiratory quotient experiments, as this forms a subject by itself. In this compilation the food consumed, the length of the experimental period, and the daily or average balance of income and outgo have been quoted in detail. The material has been arranged in convenient form for reference and the tabular matter is supplemented by text in which the experiments are described, and the objects sought, the experimental methods employed, and the conclusions drawn are noted in more or less detail.

## RECENT WORK IN AGRICULTURAL SCIENCE.

### CHEMISTRY.

**Methods of estimating fat**, O. POLIMANTI (*Arch. Physiol. [Pflüger]*, 70, Nos. 7-8, p. 366).—In connection with other work the author compared different methods of estimating fat. Extraction with ether by the Soxhlet method did not give satisfactory results. The author found, however, that by shaking finely powdered substances in a shaking machine with ether for two hours all the fat was extracted. Better results were obtained when 2 cc. of metallic quicksilver was added. For instance, 2 gm. of meat meal was shaken with 200 cc. of ether for two hours. The fat was determined in an aliquot portion of the ether solution, and the same amount was obtained as when the same material was extracted for forty-eight hours with a Soxhlet apparatus and afterwards digested and extracted according to Dormeyer's method. Carbon disulphid, petroleum ether, benzol, chloroform, and different mixtures of alcohol and ether were tried, but were found to be inferior to ether as a reagent for extracting fat by the above method.

**The lecithin content of certain plant seeds and oil cakes**, E. SCHULZE (*Landw. Vers. Stat.*, 49 (1897), No. 3, pp. 203-214).—In view of the criticism of the author's method of extracting lecithin, tests of the accuracy of the method were made. The lecithin content of certain plant seeds and oil cakes was determined by the author in connection with E. Steiger and S. Frankfurt. In the author's opinion, the method proposed by him gives satisfactory results provided the substance is finely pulverized before treating it with alcohol. The lecithin content of the seeds and feeding stuffs examined was as follows:

*Lecithin content of different seeds and feeding stuffs.*

	Lecithin content. <sup>1</sup>		Lecithin content. <sup>1</sup>
	<i>Per cent.</i>		<i>Per cent.</i>
Blue lupine .....	2.19	Hemp .....	0.73

<sup>1</sup> Calculated from the amount of phosphorus in the ether-alcohol extract.

A considerable quantity of lecithin was prepared from wheat sprouts. This was found to be identical with that obtained from other sources.

**A new method for determining crude fiber in foods and feeding stuffs, J. KÖNIG** (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 1898, No. 1, p. 3).—The author states that the Weende method gives altogether too high results, since as high as 40 per cent of the pentoses contained in plants remain undissolved in the crude fiber; and that Schulze's method leaves as high as 30 per cent of the pentoses undissolved. By the use of glycerin containing sulphuric acid the author has obtained results which agree well and are believed to be more accurate. Three grams of air-dry material are mixed in a 500 cc. porcelain dish with 200 cc. of glycerin (1.23 sp. gr.) containing 4 gm. of concentrated sulphuric acid, and heated for one hour in a steam-pressure apparatus at three atmospheres. The contents of the flask are diluted with 200 to 250 cc. of boiling water and filtered while hot on an asbestos filter, the residue being washed with 300 to 400 cc. of boiling water, with 50 cc. of warm alcohol (about 93 per cent), and finally with a warm mixture of alcohol and ether until the filtrate is colorless. The filter and contents are dried and weighed, incinerated, and the difference in weight before and after incineration taken as crude fiber. In the absence of a pressure apparatus the determination can be made in a 600 cc. flask of Schott glass, heating one hour with a reflux condenser at 131 to 133°, *i. e.*, maintaining the glycerin mixture at boiling. The crude fiber obtained by this method is said to contain a maximum of 6.62 per cent of pentoses and 0.1 to 0.4 per cent of nitrogenous substance.

**Note on the determination of nitrogen as practiced at the agricultural experiment station of Aisne, France** (*Bul. Sta. Agron. Laon*, 1897, pp. 58-62, fig. 1).—The modification of the Kjeldahl method which is used at this station is as follows: To 1 gm. of finely ground material in a 200 cc. flask add a small drop of mercury (about  $\frac{1}{2}$  gm.) and 20 cc. of 66° sulphuric acid, and heat on a sand bath until the substance is completely dissolved. This usually requires about half an hour. Then bring gradually to boiling temperature, heating first over a wire gauze, then in the direct flame of the lamp. In about three-quarters of an hour the solution is completely decolorized. Wash the contents of the digestion flask into a liter distillation flask with about 100 cc. of distilled water, add in two portions 100 cc. of caustic soda solution of a density of 1.375 and 5 cc. of a solution of 200 gm. of sodium sulphid in 1 liter of water, then add 15 to 20 gm. of granulated zinc and connect the distillation flask with a bulb tube, the lower arm of which is 1 cm. in diameter and the upper end sharply bent downward to connect with a long tube 4 to 5 mm. in diameter which dips into the flask containing the standard acid. This standard acid contains 35 gm. of pure sulphuric acid per liter, corresponding exactly with 1 centigram of nitrogen. The caustic potash solution used for titrating the acid corresponds, volume for volume, with the acid, thus avoiding the necessity of calculating results.

**The Wagner method of determining citrate-soluble phosphoric acid in Thomas slag,** B. SJÖLLEMA (*Chem. Ztg.*, 21 (1897), No. 96, pp. 999, 1000).—The following modification of the citrate method is used: To 50 cc. of the clear filtrate obtained by the Wagner process add 50 cc. of an alkaline citrate solution, prepared by dissolving 500 gm. of citric acid in 4 liters of ammonia of 0.95 specific gravity and making up to 5 liters, and 15 cc. of magnesia mixture each 2 liters of which contain 110 gm. of magnesium chlorid, 140 gm. of ammonia chlorid, and 700 cc. of ammonia of specific gravity 0.96. Shake for ten minutes in a rotary apparatus, allow to stand for two hours or until the following day, and then filter and determine the phosphoric acid in the usual way. The results by this method agree very satisfactorily with those obtained by the Wagner molybdic method. In a few cases the results were too high on account of the separation of silica. This was noted especially in cases where the filtration was particularly slow.

**The valuation of phosphatic fertilizers on the basis of their content of citrate-soluble phosphoric acid,** P. WAGNER (*Chem. Ztg.*, 21 (1897), No. 87, pp. 905-911).—The history of the method of determining citrate-soluble phosphoric acid is traced and the agreement between the results obtained by this method and by experiments with plants is discussed, especial attention being given to the use of the method in determining the fertilizing value of Thomas slag. Experiments are reported which show a uniform and very close agreement between the citrate-solubility of different phosphates, especially Thomas slags, and the actual availability of the phosphoric acid to plants. The precautions which must be observed in order to get concordant results by this method are explained in detail, strict conformity with the letter of the directions being especially emphasized. In a series of tests of the direct citrate method for determining phosphoric acid in the Wagner extract, it was found that unless the freshly prepared extract was used the results were too high in case of slags rich in silica on account of the separation of the silicic acid in the precipitate. The error thus introduced was considerable in case of extracts only two hours old and increased with the age of the extract. If the alkaline citrate solution was added to the fresh extract and the solution shaken, no separation of silicic acid occurred for eight or more hours.

The conclusion drawn from these tests is that in the use of the direct citrate method for determining phosphoric acid in the Wagner extract, a mixture of the alkaline citrate solution and magnesia mixture should be added to the fresh extract, but that the solution may be filtered immediately or it may stand an hour or more after precipitation before filtration without fear of separation of silicic acid. The mixture used should be prepared as follows: Dissolve 200 gm. of citric acid in 1 liter of 20 per cent ammonia. Mix this solution with 1 liter of the ordinary magnesia mixture. The determination of phosphoric acid is made as follows: To 50 cc. of the freshly prepared extract add 50 cc. of the

above mixture and shake for one-half hour in a rotary apparatus. Filter at once, or allow to stand not longer than one hour before filtration, and proceed in the usual way.

**The determination of citrate-soluble phosphoric acid in Thomas slag,** O. BÖTTCHER (*Chem. Ztg.*, 21 (1897), No. 95, pp. 993-995).—This is a discussion of Wagner's paper above noted. The author claims priority in pointing out the necessity for precipitation in the fresh extract in order to avoid error due to the separation of silicic acid in the citrate method of determining the phosphoric acid in the Wagner extract. Experimental data are reported to support the claim that Wagner's molybdic method is subject to the same errors due to separation of silicic acid that have been found to affect the accuracy of the citrate method under certain conditions and that the citrate method as modified by the author<sup>1</sup> is reliable when applied to the determination of phosphoric acid in the Wagner extract. It is also claimed that, contrary to Wagner's statement (see above), an error may be introduced by allowing the solution to stand for two hours after precipitation before filtering.

**A new method of absolute measurement of gases,** O. BLEIER (*Ber. Deut. Chem. Gesell.*, 30 (1897), No. 19, pp. 3123-3131, figs. 2).

**On an organic phosphorus compound which yields inosite on decomposition,** E. WINTERSTEIN (*Ber. Deut. Chem. Gesell.*, 30 (1897), p. 2299; *abs. in Bul. Soc. Chim. Paris*, 3. ser., 20 (1898), No. 4, p. 239).—Along with the proteid substances extracted from cereal grains with a 10 per cent sodium chlorid solution was obtained a compound which contained 13 per cent of magnesium oxid and 42 per cent of phosphoric acid ( $P_2O_5$ ) and yielded inosite when treated with hydrochloric acid. The exact chemical constitution of the compound was not determined.

**Chemical physiological investigation of sugar cane,** F. A. F. C. WENT (*Jahrb. Wiss. Bot. [Pringsheim]*, 31 (1898), No. 3, pp. 289-344, pl. 1).

**Inversion of sugar by neutral salts in the presence of glucose,** H. C. PRINSEN-GEERLIGS (*Meded. Proefstat. Suikerriet West Java*, 31, pp. 1-12).

**Impure copper sulphate,** H. C. PRINSEN-GEERLIGS (*Meded. Proefstat. Suikerriet West Java*, 31, pp. 17, 18).

**On the determination of oxygen dissolved in water,** ALBERT-LEVY and F. MARBOUTIN (*Bul. Soc. Chim. Paris*, 3. ser., 19 (1898), No. 4, pp. 119-151).

**Researches on the rapid determination of manganese in plants and humus soils by a colorimetric method,** P. PICHARD (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 7, p. 550).—Incinerate, fuse with potassium or sodium carbonate, add a little dilute nitric acid, place in a test tube with minium or lead bioxid, add a little water and some pure nitric acid, and boil. The presence of manganese will be shown by the rose color of the solution.

**A source of error in the Kjeldahl nitrogen determination,** T. FREUNDLICH (*Chem. Ztg.*, 21 (1897), No. 77, p. 781).—Reports experiments which lead to the conclusion that there is little danger of soda solution being carried over in the process of distillation if the tube fitted in the top of the flask be carried up sufficiently high before it is bent. It is suggested that the neglect of this precaution or the long period of distillation accounts for the errors noted by Sjöllema.<sup>2</sup>

**Report of the city chemist of Christiania, Norway, for the year 1896**, L. SCHMELCK (*Christiania*, 1897, pp. 16).

**Division of chemistry**, A. M. PETER (*Kentucky Sta. Rpt. 1896*, pp. XI-XXIII).—Analyses of 19 samples of butter made on the station farm; sugar and food constituents in 21 samples of sorghum and 18 of sugar beets; food constituents in 1 sample each of horseweed (*Ambrosia trifida*) and germ feed; and the fertilizing constituents in 5 samples of tobacco grown on the station grounds with different fertilizers, 7 samples of tobacco stalks, and 1 sample each of tobacco extract refuse, nitrate of potash, double potassium and magnesium carbonate, and wheat bran are reported, with the results of the examination of 6 samples of mineral waters and 1 of calcareous sandstone.

**The examination of agricultural and commercial products**, J. KÖNIG (*Die Untersuchung landwirtschaftlich und gewerblich wichtiger Stoffe*. Berlin: Paul Parey, 1898, 2. ed., pp. 824, pl. 1, figs. 248).—A revised edition of this practical laboratory manual. It contains chapters on the analysis of soil (including stone, lime, and cement); fertilizers; feeding stuffs; milk and dairy products; fats and oils; raw materials used in the manufacture of sugars, spirits, and vinegar; beer and brewing materials; wine; water, and wool. Chapters are also included on the testing of seeds, the preparation of laboratory reagents, and the injuries to vegetation due to the smoke, vapors, and dust from manufactories. Numerous tables are included.

## BOTANY.

**Report of the botanist**, H. GARMAN (*Kentucky Sta. Rpt. 1896*, pp. XLVIII-XXIV, pls. 2).—A considerable portion of the botanist's attention has been devoted to a study of the woolly mullein (*Verbascum phlomoides*), and attempts have been made to secure its eradication. It seems to be confined to very few counties of the State. It is believed that the methods adopted were successful in greatly reducing the number of the weeds. Concerning the ease with which the weed may be destroyed and the slowness with which it seems to be disseminated, the author believes that another season's work would practically eradicate it. In appearance the woolly mullein somewhat resembles the common mullein of the fields.

Some attention was also given during the season to the subject of broom rape of hemp and tobacco, and it was found that in addition to

being parasitic on the roots of these plants it also attacks cabbage, rape, and shepherd's purse. All attempts to cause it to establish itself on watermelon, clover, wheat, and potatoes have failed.

Brief notes are given on the grass plats planted at the station to test the quality, yield, hardiness, rate of growth, etc., of different species of cultivated and native forage plants.

Mention is also made of cooperative experiments with the Division of Forestry of this Department in which the rate of growth, quality, etc., of trees of the same species grown from seeds collected in different parts of the United States are to be tested.

**Investigations on the ripening of fleshy fruits,** C. GERBER (*Ann. Sci. Nat. Bot.*, 8. ser., 1 (1897), No. 1-6, pp. 1-280, pls. 2).—The author has made a study of the changes taking place in fleshy fruits during their ripening. The principal subjects of the extensive experiments were apples, grapes, and oranges, representing the malic, tartaric, and citric acid groups; the Japanese persimmon, representing the tannin-containing fruits; and the banana as a type containing an abundance of starch. In addition to these comparisons were made with alkekengi, mangoes, apricots, peaches, pears, plums, melons, etc. Culture experiments with molds were maintained to verify the conclusions relative to transformations by the fruits. Whatever substances were noted in the fruit the same were added to the culture media in which *Sterigmatozystis nigra* was grown, and parallel experiments were conducted often with identically the same results. The gaseous exchange between the fruits and air was noted at different temperatures ranging from 0° to 30° C., such temperatures occurring either during the day or the night at the time of the normal maturity of the fruit. As far as possible the experiments were conducted with whole and sections of the fruits at different degrees of ripeness on and off the tree and during the mellowing of the fruit. After noting the respiration the fruits were subjected to chemical analysis to determine the presence of acids, tannin, starch, sugar, etc.

Contrary to the respiration of ordinary plants, fleshy sweet fruits, during a considerable portion of their development, give off a greater volume of carbon dioxide than the amount of oxygen taken up. The author considers the respiratory quotient under two heads—the acid quotient due to the presence of acids, and the fermentation quotient, by which is meant the respiration resulting in the production of alcohol, through an insufficient quantity of oxygen brought to the cells. These two respiratory quotients differ in respect to time and temperature at which each is most active, their value and intensity, and, by their chemical results, the fermentation quotient indicating the formation of alcohol and essential oils, while nothing comparable is indicated by the acid quotient.

The principal modifications found during the maturing of the fruits are shown in the chemical changes observed in the acids, tannins,

starch, and sugar. The acids are partially transformed into carbohydrates. This is shown by the culture experiments with the mold and also from the fact that the amount of sugar found in the ripe fruit equals the starch and acids lost. The tannins are completely destroyed by oxidation, there being no evidence to show that it adds to the carbohydrate content of the well-ripened fruit. The starch is transformed into sugar, as may be seen by comparing the relative amounts of the two carbohydrates from time to time during maturation. The sugars depend, as has already been shown, upon the starch and acids and in those fruits in which the fermentation quotient continues after maturity part of the sugar is transformed into alcohol, volatile acids, and perfumes.

The following practical deductions are drawn from the experiments: As acids and tannins disappear rapidly at high temperatures it is possible to hasten the ripening of apples, grapes, oranges, Japanese persimmons, sorbus, medlars, pears, etc., by exposing them to higher temperatures. The maturity of some apples, grapes, cherries, oranges, etc., may be retarded by cold storage at a temperature of about  $0^{\circ}$  C. The fruits of the sorbus, medlar, Japanese persimmon, etc., since they continue the fermentation quotient after maturity, can not be preserved for any considerable length of time either at a high or low temperature. The necessity for a high temperature for the transformation of the citric and tartaric acids and the oxidation of malic acid at a low temperature explain how apples, sorbus, medlars, and fruits containing malic acids mature best in cool climates, while grapes and oranges require higher temperatures. They also explain why the fruits of the apple, etc., readily ripen off the tree, while grapes and citrus fruits in general ripen best on the parent plant. The latter fruits may be ripened successfully off the plant if the temperature be sufficiently increased.

**Respiration of plants at low temperatures,** E. ZIEGENBEIN (*Naturw. Wchnschr.*, 1896, No. 9; *abs. in Ann. Agron.*, 23 (1897), No. 7, pp. 333, 334).—It is stated that Krussler in 1888 showed that cuttings of *Rubus*, leaves of *Phaseolus vulgaris*, *Ricinus communis*, and *Prunus lauro-cerasus* continued to respire at  $0^{\circ}$  C. The author shows that carbon dioxid is liberated by the germination of *Lupinus luteus* and *Triticum vulgare* at low temperatures. In the case of the lupine 100 gm. of germinating seed gave off 5.78 mg. carbon dioxid per hour at  $-2^{\circ}$  C., and 100 gm. of sprouting wheat at  $0^{\circ}$  liberated 7.96 mg. carbon dioxid per hour.

**The action of alcohol on the germination of fungus spores,** P. LESAGE (*Ann. Sci. Nat. Bot.*, 8. ser., 3 (1896), pp. 151-159, fig. 1).—Experiments with *Penicillium glaucum* and *Sterigmatocystis nigra*, in which cultures of the spores were suspended in a special form of apparatus, show that alcohol vapors up to concentrations of from 6 to 8 per cent acting alone do not prevent the germination of the spores. In the presence of watery vapor the limit is raised to about 15 per cent. Beyond these limits alcoholic solutions retard germination, and, if con-

tinued for a considerable time, kill the spores. The toxic action is exerted in a very short time when the alcohol acts alone, or more slowly in the presence of vapor of pure water. Increasing the strength of the solution or raising the temperature rapidly increases the toxic action.

Lessons with plants, L. H. BAILEY (*New York: The Macmillan Co.*, 1898, pp. 491, figs. 446).—This consists of popular suggestions for seeing and interpreting some of the common forms of vegetation. It is a valuable contribution to the nature studies for primary and secondary schools.

## FERMENTATION—BACTERIOLOGY.

The occurrence of alcoholic ferments in nature and their transportation, A. BERLESE (*Riv. Patol. Veg.*, 5, pp. 211, 295, 354; *abs. in Centbl. Bakt. u. Par.*, 2. Abt., 3 (1897), No. 21-22, pp. 592-597).—The author reports the results of investigations of soil from vineyards and from neighboring woods; bark from grapevines and from trees; leaves, flowers, fruit, etc., of the grape and other plants; insects, small animals, and the air, for the presence of the ferments so necessary to wine making. The organisms of alcoholic fermentation were quite commonly found, although their occurrence was noticed at different times for different hosts. In April and June, *Saccharomyces apiculatus*, *S. ellipsoideus*, *S. pasteurianus*, forms of *Torulopsis*, *Mucor dematium*, etc., were found

in the vineyard and wood soil, occurring at depths of 10 to 15 cm. in the vineyard and  $\frac{1}{4}$  to 36 cm. in the woods. Investigations showed their presence on the bark of oak and olive trees and elsewhere. None were found on the young grapes nor their peduncles in June, nor were any observed in the air during April or May, but in June and July *S. apiculatus* was found in the air.

Various insects were found to play a very important part in the distribution of the organisms. In general it is claimed that the alcoholic ferments are carried to the grapes by ants, flies, and gnats; they can pass uninjured through the digestive canal of the Diptera. They are very active in the intestines of the Diptera, the temperature being suited to their development.

**Concerning cellulose fermentation**, V. OMELIANSKI (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 25, pp. 1131-1133).—In a previous paper (E. S. R., 9, p. 922) the author gave the principal characteristics of the ferments of pure cellulose. In the present one the products of the decomposition of cellulose by fermentation are given.

**Cellulose enzymes**, F. C. NEWCOMBE (*Bot. Centbl.*, 73 (1898), No. 4, pp. 105-108).—The author presents a preliminary paper on studies on cellulose enzymes. In addition to those obtained from *Peziza* and barley by DeBary, Marshall Ward, and Morris and Brown, the author reports the isolation of enzymes from *Lupinus albus*, *Phanix dactylifera*, and *Aspergillus oryza* that are capable of breaking down cellulose.

**A study of the ferment which coagulates blood (fibrin ferment or thrombose), and the power of propeptones to prevent coagulation**, A. DASTRE and N. FLOR-ESCO (*Arch. Physiol. Norm. et Path.*, 5. ser., 9 (1897), pp. 216-228).

**Remarks on fibrin ferment and the alkalinity of peptic plasma**, J. ATHANASIU and J. CARVALLO (*Arch. Physiol. Norm. et Path.*, 5. ser., 9 (1897), pp. 375-384).

**On the action of diastase**, E. DUCLAUX (*Ann. Inst. Pasteur*, 11 (1897), No. 10, pp. 792-800).—A critical review of the subject.

## ZOOLOGY.

**Indian wild cattle: The tsine and the gaur (miscalled bison)**, POLLOK (*Zoologist*, 4. ser., 2 (1898), No. 13, pp. 1-10).—The tsine (*Bos sondaicus*) and the gaur (*B. gaurus*) are discussed by a hunter. Two distinct forms of the latter species are found, known as the gaur and the gayal. At a distance both look alike, but the gaur's head has a semicylindrical crest and a concave forehead. The head of the gayal has neither. In the gaur again there are two varieties, distinguished by the natives as jungle cow and jungle buffalo. One has a large dewlap, the other scarcely any, or none. When captured the animals, after passing through a period of great pugnacity, become very tame.

**Preliminary description of a new mountain sheep from the British Northwest Territory**, J. A. ALLEN (*Bul. Amer. Mus. Nat. Hist.*, 9 (1897), pp. 111-114, pls. 2).—The species *Oris stonei* differs from *O. dalli* in being dark gray or blackish brown. This coloration also distinguishes it from *O. cervina*, which is umber brown or wood brown. It is also a smaller animal than the latter. Three specimens were obtained from the head waters of the Stickeen River, in British Northwest Territory, near the Alaskan boundary.

**Description of a new deer (*Dorcélaphus texanus*) from Texas and northern Mexico**, E. A. MEARNS (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 23-26).

**Descriptions of six new ground squirrels from the Western United States**, C. H. MERRIAM (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 69-71).—*Spermophilus oregonus* from Swan Lake Valley, Oregon; *S. mollis stephensi* from Owens Valley, Nevada; *S. mollis yakimensis* from Yakima County, Washington; *S. mollis canus* from Wasco, Oregon; *S. tridecemlineatus alleni* and *S. tridecemlineatus texensis* from Cook County, Texas.

**Descriptions of two new skunks of the genus *Mephitis***, O. BANGS (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 31-33).—*Mephitis spissigrada* from Sumas, British Columbia, and *M. avia* from San Jose, Illinois. In general appearance the former much resembles *M. hudsonica* and *M. occidentalis*, into which two species it intergrades. The other species is small, with a very short and bushy tail and a peculiar skull. It is black everywhere except a white frontal stripe and nuchal patch and two lateral or subdorsal white stripes passing backward from the nuchal patch.

**Descriptions of the Newfoundland otter and red fox**, O. BANGS (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 35-38).—*Lutra degener*, n. sp., and *Vulpes deletrix*, n. sp.

**The eastern races of the American varying hare, with description of a new subspecies from Nova Scotia**, O. BANGS (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 77-82).—*Lepus americanus struthopus*, n. subsp.

**Description of a new rodent of the genus *Idiurus***, G. S. MILLER (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 73-76, figs. 5).—*Idiurus nacrotis* from the Cameroon district, West Africa.

**Description of a new white-footed mouse from the Mount Baker Range, British Columbia**, O. BANGS (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 83, 84).—*Peromyscus oreas*, n. sp.

**A new species of *Evotomys* from British Columbia**, V. BAILEY (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 21, 22).—A description of *Evotomys cauricus* found along the coast of British Columbia.

**Hybrids between the gamecock and the guinea fowl**, T. VILARÓ (*Bul. Amer. Mus. Nat. Hist.*, 9 (1897), pp. 225-230, pls. 3).—Six cases are described. There was a lack of any procreative tendency in both males and females. The quarrelsome disposition of the guinea fowl was preserved. The hybrids would even combine in attacks upon other fowls.

**Description of new birds from Mexico, with a revision of the genus *Dactylortyx***, E. W. NELSON (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 57-68, fig. 1).

**Twenty years' observations on the migrations of the birds of the Luxembourgish fauna, 1863 to 1894**, A. DE LA FONTAINE (*Pub. Inst. Grand Ducal de Luxembourg*, 25 (1897), pp. 238, pl. 1).—The observations are given in detail and the subject of bird migration and its causes generally discussed. The orientation of the birds is attributed to a sixth sense. The work also contains a necrological notice of the author.

**Extract from the laws of the Empire concerning the protection of birds** (*Jahresber. Ver. Naturk. Zwickau*, 1896, pp. 84-86).—The laws of the German Empire relating to the subject.

**The birds of the vicinity of Zwickau**, R. BERGE (*Jahresber. Ver. Naturk. Zwickau*, 1896, pp. 83, figs. 174).—A systematic treatment of the subject.

**The voice registers of birds**, C. W. WITCHELL (*Zoologist*, 4. ser., 2 (1898), No. 13, pp. 11-13).

**The tongues of birds**, F. A. LUCAS (*Smithson. Rpt. 1895*, pp. 1003-1020, pls. 2, figs. 13).—An anatomical study of considerable interest in which specific and individual variations are noted and figured.

**On a new *Tænia* of birds**, O. FUHRMANN (*Rev. Suisse Zool.*, 5 (1897), pp. 107-117, pl. 1; *abs. in Zool. Centbl.*, 5 (1897), No. 2, p. 46).—*Citto tænia arvicola*, n. sp., from *Anas* sp. In the genital organs, number of testes, and position of the excretory canals it is related to *C. marmota*, and in the structure of the cirrus to *C. pectinata*.

**Notes on Trematode parasites of fishes**, E. LINTON (*Reprint (No. 1133) from Proc. U. S. Nat. Mus.*, 20 (1897), pp. 507-548, pls. 15).—The new species, *Nitzschia papillosa* from *Gadus callarias*, *Octoplectanum affine* from *Paralichthys dentatus*, *Distomum larvæ* from *Macronurus bairdii*, *D. monticellii* from *Remora remora*, *D. lageniforme* from *Remora remora*, *D. foliatum* from *Mola mola*, *D. nitens* from *Tylosurus caribbeus*, *D. tenue* from *Roccus lineatus*, and *D. tenue tenuissime* from *Marone americana*, are described. In all 32 species and subspecies are listed. The other genera represented are *Tristomum*, *Diplostomum*, and *Monostomum*.

**The Myxosporidia in the musculature of the genus *Coregonus***, F. ZSCHÖCKE (*Zool. Anz.*, 21 (1898), No. 554, pp. 213, 214).—The author is of the opinion as a result of his studies that all of the Myxosporidia found in the musculature of *Coregonus* occurring in the waters of Switzerland belong to the same species. Since none of the 3 species recorded have been sufficiently described or figured the author proposes to group them all as *Myxobolus bicaudatus*, which he describes. This species is found often in large numbers in the connective tissue of the musculature of *Coregonus*.

**The Arcturidæ in the U. S. National Museum**, J. E. BENEDICT (*Proc. Biol. Soc. Washington*, 12 (1898), pp. 41-51, figs. 9).—A key to the species of the genus *Arcturus* and descriptions of several new species are given.

Work in zoology in 1896 (*Zoologist*, 4. ser., 2 (1898), No. 13, p. 39).—According to the enumeration of the Zoological Record, in 1896 there appeared 291 papers dealing with mammals, 639 with birds, 307 with reptiles and batrachia, 240 with fishes, 30 with tunicates, 391 with mollusks, 20 with brachiopods, 21 with bryozoa, 206 with crustacea, 114 with arachnids, 56 with myriapods and prototracheates, 1,264 with insects, 251 with vermes, 122 with coelenterates, 57 with sponges, and 190 with protozoa. According to Dr. Sharp no less than 8,907 distinct species and 1,040 genera and subgenera were described as new.

### METEOROLOGY.

**Special meteorological features of the year 1895, F. HOUDAILLE** (*Ann. École Nat. Agr. Montpellier*, 9 (1895-'96), pp. 17-25, charts 21).—The special meteorological features (temperature, pressure, precipitation, humidity, evaporation, cloudiness, wind movement, etc.) of each month of the period from December, 1894, to November, 1895, inclusive, are charted and discussed and their influence on the growth of the vine during the season of 1895 briefly noted. The most marked features of the season were a prolonged period of rainfall during the summer and a maximum temperature in September, instead of July or August as usual. As a result of these conditions there was an unprecedented invasion of mildew, due to the high temperature and great humidity, but a very superior quality of grapes, due to the prolonged high temperature during the period of ripening.

**The daily measurement of dew in 1895, F. HOUDAILLE** (*Ann. École Nat. Agr. Montpellier*, 9 (1895-'96), pp. 26-32).—Measurements during the period from December, 1894, to November, 1895, inclusive, of the dew deposited upon a glass plate with an area of 25 sq. cm., are tabulated and discussed and compared with similar observations in previous years. A summary of the monthly dew measurements during 1893, 1894, and 1895 is given in the following table:

*Depth of dew during each month of 1893-'95.*

	1893.	1894.	1895.	Average, 1893-'95.
	<i>Mm.</i>	<i>Mm.</i>	<i>Mm.</i>	<i>Mm.</i>
January .....	0.448	0.559	0.038	0.348
February .....	.072	1.114	.104	.430
March .....	.834	.854	.436	.708
April .....	.696	.608	.536	.613
May .....	.284	.247	1.168	.564
June .....	.648	.874	.398	.640
July .....	.140	.404	.562	.389
August .....	.968	.952	.675	.865
September .....	.676	.660	1.078	.805
October .....	1.602	1.096	.580	1.093
November .....	.310	.912	.557	.593
December .....	1.026	1.466	.368	.953

**Causes of the maximum rates of evaporation in the climate of Montpellier, F. HOUDAILLE** (*Ann. École Nat. Agr. Montpellier*, 9 (1895-'96), pp. 286-295, figs. 2).—Observations during each month of 1896 on velocity of evaporation, temperature, hygrometric condition

of the air, and velocity of the wind are recorded, as well as the monthly averages of evaporation for ten years (1875-'84). These observations were made by Piche and self-recording evaporimeters over a surface of water in a metallic dish 10 sq. em. in area. A summary of the results is given in the following table:

*Mean maximum temperature, humidity of air, and velocity of wind.*

	Mean maximum temperature, 1896.	Humidity at 9 a. m., 1875-'88.	Velocity of wind, 1883-'96.
	Deg. C.	Per cent.	M. per sec.
January.....	11.47	81.77	4.24
February.....	14.97	76.39	4.76
March.....	18.88	.70	4.95
April.....	21.59	.67	4.87
May.....	26.01	.62	4.51
June.....	28.63	.58	4.49
July.....	33.25	.56	4.41
August.....	30.07	.57	3.83
September.....	27.01	.66	3.76

**Variations in winds in the climate of Montpellier,** F. HOUDAILLE (*Ann. École Nat. Agr. Montpellier, 9 (1895-'96), pp. 161-175, figs. 2*).—This is a discussion, with tabulated record of observations from 1883 to 1896, on variations in the velocity and force of winds. The following formula is used for expressing the force of winds:  $P = KV^2$ ,  $V$  representing the velocity and  $K$  a coefficient varying with the form and size of the surface exposed to the wind. For a surface of 1 square meter  $K$  is assumed to be 0.125. The average annual velocity of wind observed at Montpellier is 4.36 meters per second. The force per square meter is, therefore, 2.376 kg. From this it is calculated that the amount of force per square meter available for windmills is  $2.376 \times 4.36 = 10.36$  kg., one-half of which may be utilized.

**Actinometric observations during the year 1895,** A. CROVA (*Ann. École Nat. Agr. Montpellier, 9 (1895-'96), pp. 145-149, charts 2*).—The number of hours of sunshine at the meteorological observatory at Montpellier during the year 1895 were as follows: Winter, 526 hours 31 minutes; spring, 585 hours 16 minutes; summer, 739 hours 2 minutes; autumn, 434 hours 44 minutes; total, 2,285 hours 33 minutes. The intensity of sunlight<sup>1</sup> was least in winter, but increased gradually until the month of March, when it reached 1.2 small calories (gram-degrees). It afterwards decreased, but rose again, reaching its first maximum, 1.22 calories, in June. The second maximum, 1.3 calories, was reached in September, after which the intensity diminished until the 1st of December.

**Division of meteorology,** V. E. MUNCY (*Kentucky Sta. Rpt. 1896, pp. XXVIII-XLIII*).—Monthly summaries of observations during 1896 on temperature, atmospheric pressure, precipitation, sunshine and

<sup>1</sup>The intensity is the quantity (in small calories) of heat received in 1 minute by a black surface 1 square centimeter in extent exposed directly to sunlight.

cloudiness, wind movement, and casual phenomena are reported in tables. The principal data for the year are as follows:

*Temperature* (degrees F.).—Maximum, 95, September 18; minimum, -2, February 21; mean, 55.9; absolute range, 52; mean daily range, 17.2. *Atmospheric pressure* (inches).—Highest, 29.58, December 24; lowest, 28.21, February 21; mean, 29.03. *Precipitation* (inches), 43.29; number of days on which 1 in. or more of rain fell, 13. Clear days, 63; cloudy or partly cloudy days, 303. *Wind*.—Prevailing direction SW.

**Measurement of the coefficient of viscosity of the air**, C. FABRY and A. PEROT (*Ann. Chim. et Phys.*, 7. ser., 13 (1898), Feb., pp. 275-288, figs. 2).

**The measurement of the coefficient of diffusion of aqueous vapor in the atmosphere and of the friction coefficient of aqueous vapor**. F. HOUDAÏLLE (*Ann. École Nat. Agr. Montpellier*, 9 (1895-'96), pp. 35-126, figs. 9, charts 3).—This is a technical paper describing in detail the methods and results of determinations of these coefficients. The coefficient of diffusion of aqueous vapor at 0° found by direct measurement was  $D_0 = 0.203$ ; the coefficient of friction of air  $\eta_0 = 0.000186$ , of aqueous vapor  $\eta'_0 = 0.0000975$ .

**Description of a maximum anemometer**, F. HOUDAÏLLE (*Ann. École Nat. Agr. Montpellier*, 9, (1895-'96), pp. 5-16, figs. 3).—The instrument is described and tests of it are reported.

**Meteorological observations on the Atlantic Ocean**, PRINCE OF MONACO (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 5, pp. 373-375).

**Meteorological observations, 1896-'97**, W. B. ALWOOD (*Virginia Sta. Rpt.*, 1897, pp. 7, 8).—Tables give monthly summaries of observations on temperature, precipitation, direction of wind, and cloudiness for the period from July 1, 1896, to June 30, 1897; and, for comparative purposes, monthly summaries of observations on temperature and precipitation for five years (1893-'97). The mean temperature for the period from July 1, 1896, to June 30, 1897, was 51.56° F., the total rainfall 42.32 in. The mean temperature for the five-year period was 51.7° F., the mean rainfall 36.18 in.

**Meteorological and agricultural notes**, J. B. CHABANEIX (*Ann. École Nat. Agr. Montpellier*, 9 (1895-'96), pp. 127-140).—This is a record of observations during the period from December, 1891, to December, 1895, on temperature of the air (maximum, minimum, and average), and of the soil (at the surface and at a depth of 0.25 meter), rainfall, evaporation, humidity, direction of wind, cloudiness, frosts, and thunderstorms, with general notes on the character of the season and its influence upon the growth of crops.

**On the character of seasons and of successive years**, P. GARRIGOU-LAGRANGE (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 11, pp. 829-831).

**Climatology as distinguished from meteorology**, M. WHITNEY (*Science*, n. ser., 7 (1898), No. 161, pp. 113-115).—Climatology is defined as "the relation between the meteorological elements as measured by the development of the plant." The general relation of the principal elements may be expressed by the equation

Sunshine  $\left( \frac{\text{Temperature} \times \text{wind velocity}}{\text{Humidity} \times \text{soil moisture.}} \right) = \text{constant condition of plant growth,}$

or in still more general terms

$$(1) \quad \psi(s) \frac{\phi(t)}{\Gamma(h)} \frac{f(v)}{\Delta(w)} = k, \text{ conditions favorable for the vegetative period.}$$

$$(2) \quad \psi'(s) \frac{\phi'(t)}{\Gamma'(h)} \frac{f'(v)}{\Delta'(w)} = k', \text{ conditions favorable for the ripening or fruiting period.}$$

In these equations  $s$  = intensity of sunshine,  $t$  = temperature,  $v$  = velocity of the wind,  $h$  = relative humidity, and  $w$  = soil moisture.

Three of the elements being constant, it should be possible to determine the

approximate variations in the other best suited to different classes of plants for different periods of growth.

**The periods of plant growth and the effects of climatic conditions on plants.** J. B. CHABANEIX and P. DUCHEIN (*Ann. École Nat. Agr. Montpellier*, 9 (1895-'96), pp. 142-144, 296, 297).—This is a tabulated record of observations on the date of germination, leafing, flowering, maturity, and defoliation during 1894-'95 of 22 deciduous and 8 evergreen trees and shrubs, 5 perennial herbaceous plants, and 17 annual plants, and a similar series of observations during 1895-'96 on 22 deciduous and 8 evergreen trees and shrubs.

### WATER—SOILS.

**Tobacco soils of the United States,** M. WHITNEY (*U. S. Dept. Agr., Division of Soils Bul. 11, pp. 17, pls. 13*).—This bulletin gives a brief review of recent literature on tobacco, statistics of tobacco production in different tobacco-growing districts of the United States, meteorological conditions in the great tobacco regions, and texture and water content of typical soils of the various tobacco-growing districts.

The conclusion is drawn that there is not sufficient difference in the meteorological conditions in the different regions, as ordinarily recorded, "to explain the distribution of the different classes of tobacco, yet this distribution is probably due mainly to climatic conditions. . . .

"One must still judge, so far as the climate is concerned, mainly from the experience of others as to the class of tobacco to be raised, as the ordinary meteorological record will be of very little value in determining this point. The plant is far more sensitive to these meteorological conditions than are our instruments. Even in such a famous tobacco region as Cuba tobacco of good quality can not be grown in the immediate vicinity of the ocean or in certain parts of the island, even on what would otherwise be considered good tobacco lands. This has been the experience also in Sumatra and in our own country, but the influences are too subtle to be detected by our meteorological instruments.

"Little, therefore, can be said at the present time in regard to the suitable climatic condition for tobacco of any particular type or quality."

Next to climatic conditions the class and type of tobacco depends more largely upon the character of soil than upon any other condition. The present bulletin reports and discusses mechanical analyses of a large number of samples of soil and subsoil collected in the more important tobacco districts, and also gives records of determinations of the moisture content during several years "in one or two localities in some of the principal tobacco districts."

The results show that the cigar tobacco soils of the Connecticut Valley contain on an average considerably less than 5 per cent of clay and maintain on an average about 7 per cent of water throughout the season. "These soils are too light in texture for any of the staple farm crops. They are adapted to the quick-growing spring vegetables. . . . The conditions seem to be peculiarly adapted to a particular grade of wrapper leaf tobacco." Attention is called to the fact that a few years ago, when there was a greater demand for heavier cigars, these light soils had little or no value for tobacco, the tobacco being grown mainly on

the heavier soils and on the "meadow lands" of the Connecticut Valley. These meadow lands differ from the light tobacco soils now cultivated principally in containing a larger proportion of silt, which enabled them to maintain a water content of from 23 to 27 per cent.

The tobacco lands of Pennsylvania, which are also devoted mainly to growing cigar tobacco, are confined chiefly to a comparatively narrow belt along the Susquehanna River and to the limestone soils "typically developed in York and Lancaster counties." The amount of clay in these soils varies from 13.8 per cent in the river soils and shaly limestone soils to 29.27 per cent in the pure limestone soils. They maintain on an average about 18 per cent of water, the amount rising to 22 to 23 per cent in the heaviest limestone soils. The best wrapper leaf is produced on the lighter soils.

"The cigar tobacco district of Ohio is situated in the southwestern part of the State and includes the country bordering on the Miami River, Montgomery, Darke, and Preble counties forming the center of the district. . . . The soil is derived from drift material which has been worked over and modified by subsequent action of water." A typical soil from this region was found to contain 44.01 per cent of silt and 27.52 per cent of clay. It thus appears that the soils of this district are as heavy in texture as the limestone soils of Pennsylvania. During the season of 1897 they maintained a moisture content of a little more than 27 per cent. "It is probable that the mean water content of these soils in an average season would amount to about 23 or 24 per cent of water. The tobacco grown under these conditions is used almost exclusively as a filler leaf. . . .

"The Wisconsin tobacco is used both as a wrapper and filler leaf to some extent." It is grown on soils a typical sample of which was found to contain 36.05 per cent of silt and 22.76 per cent of clay. No determinations of the moisture content of these soils have been made.

The Cuban type of cigar wrapper and filler and some Sumatra tobacco are grown in Florida, especially in western Florida, although a new tobacco district is being opened up in the region of Fort Mead, on the peninsula. The tobacco lands of western Florida are "a light loam about 12 in. deep, resting on a heavy red clay, which is naturally well drained. The hammock soil of Fort Mead is, on the other hand, a very light, sandy soil, extending down to a very considerable depth." The red subsoils of western Florida contain about 30 per cent of clay, but maintain on an average only about 8 to 10 per cent of moisture. The hammock lands "contain on an average less than 4 per cent of clay and less than 6 per cent of silt, fine silt, and clay. They contain over 50 per cent of fine sand, so that they are relatively rather coarse and open. Notwithstanding this open texture . . . [they] contain on an average 8 per cent of water throughout the season, which is about as much as the tobacco lands of the Connecticut Valley contain. This water content, moreover, is for some reason more uniform, and the land can go

for some time without rain with no serious injury to the crops. Nevertheless the planters have been greatly benefited by judicious systems of irrigation through overhead sprays. By thus keeping the plants continually and rapidly growing, the crop will mature in 45 days from the time the plants are set out."

The soils of the cigar tobacco districts which are being developed in Texas and southern California have not been thoroughly studied, but the analyses which have been made indicate that the soils "agree very well with the finer grades of cigar tobacco lands. The general climatic conditions, however, are different." . . .

"The bright yellow tobacco used for cigarettes, plug wrappers, fillers, and cutting is grown mainly in Virginia, North Carolina, South Carolina, and East Tennessee. . . . The typical bright tobacco land consists of a loose, porous sand, containing not more than 8 or 10 per cent of clay. This sand must be at least 12 in. deep. Many areas are cultivated in which the sand extends to a depth of 5 or 10 ft. or more, and a very fine quality of tobacco is produced."

The average of analyses of 44 samples of bright tobacco soils shows that they contain about 8 per cent of clay. They maintain on an average about 7 per cent of water.

"Where the soils contain less than this the leaf is inclined to be finer in texture and to have a better color, but the yield per acre is small, and the most economical conditions on the whole are maintained by those soils having from 7 to 8 per cent of clay and maintaining on an average about 7 or 8 per cent of water. As the soil becomes heavier in texture and the amount of water increases other grades and types of tobacco are produced. . . . As the relation of the physical properties of the soil is not thoroughly understood or practically recognized by the growers, a large amount of land is now cultivated in bright tobacco which is not suited to this plant and which does not produce a good grade. On the other hand, there are large areas not at present under cultivation which could be developed into very fine tobacco lands. The typical bright tobacco soil is of little value for any of the staple farm crops, although, when suitably located near transportation lines, it is admirably adapted to the production of early vegetables, watermelons, and sweet potatoes."

The manufacturing tobacco of Virginia and North Carolina is grown principally on the red clay soils located mainly on the gabbro, gneiss, and Lafayette clays. The subsoils of these areas contain from 30 to 50 per cent of clay, and although no observations have been made on the moisture content of these soils it is probable from observations made on adjacent soils that the mean water content is not far from 20 or 22 per cent. Since the introduction of White Burley tobacco the cultivation of the heavier types of tobacco has noticeably decreased in Virginia and North Carolina. "The industry is confined now principally to small areas along rivers, streams, or creeks, and upon recent deposits which can not well be referred to any of the older geological formations and which can not well be examined without a detailed examination of the larger part of these States. . . .

"The White Burley tobacco is confined to the well-marked type of soil of the Lower Silurian limestone in central and north central Ken-

tucky and the adjacent counties of Ohio. This embraces the blue grass region of Kentucky, and it is upon these fine, fertile, blue grass soils that the White Burley is grown." The soils are all heavy clays of a uniform deep red color. The subsoils contain on an average about 30 per cent of clay. "The characteristic soil of the limestone area of Kentucky, adapted to the White Burley tobacco, as the result of several years' investigation, may be said to maintain on an average about 20 per cent of water."

Export tobacco is grown in Kentucky and Tennessee on silty soils, which are quite fertile in character. These soils are derived chiefly from the St. Louis group of the subcarboniferous. They contain from 40 to 60 per cent of silt and 22 to 23 per cent of clay, and maintain an average water content of about 15 per cent.

"The object of the daily record of moisture in the soil is not only to determine the average amount soils contain, but to determine the normal as well as the extreme variation. . . . It is possible from such records to show the character of a season. The methods of cultivation should have for their prime object the maintenance of the water supply above the line of drought, so that the growth of the plant shall receive no check. If this can not be done by the ordinary method of cultivation, irrigation must be resorted to upon such occasions, if the crop is to be maintained in its best condition."

**The moisture of the soil in 1895 and 1896, F. HOUDAILLE** (*Ann. École Nat. Agr. Montpellier, 9 (1895-'96), pp. 150-163, charts 2*).—This is a continuation of work of previous years,<sup>1</sup> and consists of monthly determinations of moisture in a calcareous clay soil with free drainage and a more compact soil, at the surface and at depths of 0.25, and 0.05, and 1 meter. The relation between the moisture in both soils, the rainfall, and evaporation is summarized in the following table:

*Relation of moisture of the soil, rainfall, and evaporation, 1895-'96.*

	Evaporation.		Precipitation (A).		Corrected evaporation (B).		A-B.		Moisture at depth of 0.25 meter.

**On the improvement of humus soils, J. DUMONT** (*Compt. Rend. Acad. Sci. Paris, 125 (1897), No. 13, pp. 469-472*).—The effect of different fertilizers on the formation of ammoniacal and nitric nitrogen was

<sup>1</sup> Bul. Met. Hérault, 1886, 1890, 1892, 1894.

observed in a humus soil containing nitrogen, 1.32 per cent; phosphoric acid, trace; lime, 0.42 per cent; and potash, 0.036 per cent.

The results of the observations on the production of nitric nitrogen were as follows:

*Nitric nitrogen produced in 1,000 grams of soil in 40 days.*

	Mg.
Check .....	2.8
Potassium carbonate (0.1 per cent) .....	57.8
Peat ashes (0.5 per cent) .....	10.2
Unleached ashes (0.5 per cent) .....	19.0
Leached ashes (0.5 per cent) .....	3.3
Calcium carbonate (2 per cent) .....	5.3
Marly clay (2 per cent) .....	7.5
Burnt clay (2 per cent) .....	7.0
Potassium sulphate (0.1 per cent) and calcium carbonate (2 per cent) .....	32.5
Potassium chlorid (0.1 per cent) and calcium carbonate (2 per cent) .....	38.0
Potassium chlorid (0.1 per cent) and slag (5 per cent) .....	41.5

The results of the observations on the formation of ammoniacal nitrogen were as follows:

*Ammoniacal nitrogen produced in 1,000 grams of soil in 24 days.*

	Mg.
Check .....	4.0
Potassium carbonate (1 per cent) .....	15.0
Potassium carbonate (0.5 per cent) .....	40.0
Potassium carbonate (0.25 per cent) .....	62.0
Potassium carbonate (0.1 per cent) .....	82.0
Sodium carbonate (1 per cent) .....	46.0
Sodium carbonate (0.5 per cent) .....	4.7
Calcium carbonate (1 per cent) .....	130.0
Potassium chlorid (0.5 per cent) and slag (1 per cent) .....	96.0
Potassium chlorid (0.25 per cent) and slag (0.5 per cent) .....	96.0

The best results were obtained with the mixture of muriate of potash and slag, which has also been successfully applied in practice. The alkaline carbonates in small amounts favored the production of both ammoniacal and nitric nitrogen, but the action of both the ammonia and nitric ferments was checked by the application of large amounts of these carbonates. Calcium carbonate exerted little influence except when used in connection with potassic fertilizers, the effect in this case probably being due to the potassium carbonate formed by double decomposition. The vigorous action of the potassium carbonate is attributed to the power of forming potassium humate, which readily undergoes nitrification. This formation of humates appears to be an indispensable condition in improving the fertility of humus soils, and is probably best secured by using a mixture of potash salts and calcium carbonate, which, as stated above, yields potassium carbonate in the soil. If the soil is already rich in potash, the desired result may be accomplished

by simply adding lime, which gradually sets the soil potash free. If the soil is poor in potash the potassic fertilizer should be used in connection with a relatively small amount of lime, or of slag if phosphoric acid is also deficient.

**On the question of the decomposition of nitrates by bacteria,** S. A. SEWERIN (*Centbl. Bakt. u. Par., 2. Abt., 3 (1897), Nos. 19-20, pp. 504-517; 21-22, pp. 554-563, figs. 3*).—An account is given of culture experiments with 29 different organisms isolated from horse manure in previous investigations of the author on denitrification.<sup>1</sup> Of these 29 cultures 3 were strictly anaerobic, 1 was a facultative anaerobe, and 25 strictly aerobic. The culture medium used was meat peptone bouillon containing 0.3 per cent sodium nitrate. Cultures were made in Pasteur tubes containing 20 cc. of the bouillon which were kept at 30° C. temperature for ten days in a thermostat. At the end of that time the different cultures were tested for the presence of nitrates and nitrites. In 2 cases no reaction was obtained for either nitrites or nitrates, showing that denitrification was complete. In 9 cases no nitrates were found, but nitrites were abundant. In 18 cases the nitrates were apparently unaltered. In further experiments with the 9 cultures which formed nitrites it was found that when the proportion of nitrate in the culture medium was reduced to 0.1 per cent, 2 of the cultures destroyed all traces of both nitrates and nitrites in ten days; the remaining 7 transformed the nitrates into nitrites, but did not reduce the nitrites in that time. Of these 7 organisms 4 were microbacteria, 1 was a rod-shaped bacterium, 1 a coccus, and 1 *Bacillus indicus*. The different organisms are described in detail and experiments in different culture media under different conditions are reported, especial attention being given to a comparison of the reducing power for nitrates of the author's culture No. 3 and *Bacillus pyocyaneus*. The latter experiments showed that both organisms rapidly reduce nitrates, a part of the nitrogen apparently being used to form organic compounds. With moderate surface aeration a very small amount of the nitrogen was converted into ammonia. By far the greater part of the nitrate, however, was evidently reduced to free nitrogen or oxids of nitrogen. The reduction of nitrates was delayed in each case by the admission of air and by the formation of nitrites and alkali by the activity of the organism. It appears from these experiments that these organisms may be injurious in the soil in destroying nitrates. The precaution to be taken against their harmful activity is thorough aeration of the soil by proper cultivation.

**The evaporation of water from water surfaces, from the soil, and by vegetation,** E. CANESTRINI (*Atti Soc. Veneto-Trentina Sci. Nat., 2. ser., III, No. 2*).

**Soil classification especially as applied to Russia,** N. SSIBIRZEFF (*Ann. Géol. et Minéral. Russia, 2 (1897), No. 5, pp. 73-78*).

<sup>1</sup>Centbl. Bakt. u. Par., 2. Abt., 1 (1895), pp. 97, 160.

**Study of the soils of Russia**, N. SSIBIRZEFF (*Mém. Congrès. Géol. Internat., 1897, No. 5, pp. 73-125*).

**Soil temperatures with and without coverings of plants and snow**, H. WILD (*Mém. Acad. Impér. Sci. St. Pétersbourg, S. ser., Classe Phys. Math., 5 (1897), No. 8*).

**Sampling of soil for analysis**, H. LAGATU (*Prog. Agr. et Vit., 28 (1897), No. 47, pp. 603-606, fig. 1*).—A trench is dug to a depth of 0.6 meter. On the vertical side of this the character of the different soil layers is noted. A rectangular section is first taken to a depth of 0.3 meter, mixed, and from it a 2 kg. sample taken. The next 0.3 meter of the section is sampled in the same way and ordinarily taken as representing the subsoil. The latter rule is varied if the preliminary examination shows the soil to vary sharply at less than 0.3 meter. More than 2 kg. is necessary in very rocky soils.

**Sampling of alkaline soils**, E. W. HILGARD and R. H. LOUGHRIDGE (*Ann. Sci. Agron., 1897, II, No. 3, pp. 394-431, dgms. 6*).—A translation by J. Vilbouchevitch of an article in the Annual Report of the California Station for 1894-95, p. 37 (E. S. R., 8, p. 677), entitled "The distribution of the salts in alkali soils."

**Nitrogen and forest growth**, E. HENRY (*Ann. Sci. Agron., 1897, II, No. 3, pp. 359-381*).—A general discussion, based mainly upon the work of others, of the causes of gain or loss of nitrogen in forest soils, especial attention being given to fixation of nitrogen by micro-organisms. It is shown that forest soils are enriched in nitrogen and mineral matter.

**Moors and moor culture in Bavaria**, A. BAUMANN (*Forstl. Naturw. Ztschr., 6 (1897), No. 2, pp. 393-409; 7 (1898), No. 2, pp. 49-72, pl. 1, figs. 2*).

**On culture trials on marshy soils at Herrenäs (Finland)**, M. VON ESSEN (*Biet, 18 (1897), No. 12, pp. 323-335*).

**On so-called poor soils and the crops they can produce**, I. G. AGARDH (*K. Landt. Akad. Handl. Tidskr., 36 (1897), No. 5, pp. 267-287*).

**Influence of forests on subterranean water**, P. OTOTZKY (*Ann. Sci. Agron., 1897, II, No. 3, pp. 455-477, pls. 2*).—This is a translation from the Russian giving the results of a hydrological survey in the steppes region. The conclusion is reached that, physico-geographical conditions being the same, the level of ground water is lower in the forests than in the adjacent steppes or in general in neighboring open spaces. The level falls as forests are approached, the fall sometimes being very sudden, and it is more marked in case of old forests than new. It was noted also that at the surface of the ground water had an incline opposite that of the soil.

## FERTILIZERS.

**Absorptive powers of litter for ammonium carbonate**, N. PAS-SERINI (*Ann. R. Acad. Georgifili, 20 (1897); abs. in Ann. Agron., 24 (1898), No. 2, p. 92*).—Instead of testing the absorptive power with water, as is usually done, the different kinds of litter, straw of cereals and leguminous plants, leaves of trees, peat, etc., were treated with a solution of ammonium carbonate of known strength, kept for two hours in a closed flask and the amount of ammonium carbonate absorbed noted. The cereal straws showed a low absorptive power, although varying greatly among themselves, barley, oat, and rice straw having the highest absorptive power. Cutting or grinding had but little effect upon the absorptive power of wheat straw, but increased that of corn-stalks seven times. The absorptive power of the litter of leguminous plants was much greater than that of cereal straws; that of the leaves

(except pine straw) was still higher, due, according to the author, to the acid (tannin, etc.) they contain. Wood moss ranked with leaves in absorptive power, and peat of good quality stood at the head of the list.

**Analyses of commercial fertilizers, L. L. VAN SLYKE** (*New York State Sta. Bul. 129, pp. 351-121*).—Of the 735 samples, representing 500 different brands of commercial fertilizers collected during the spring of 1897, 400 were complete fertilizers. The average composition of the latter is shown in the following table:

*Average composition of complete fertilizers.*

	Per cent guaranteed.			Per cent found.			Average per cent found above guarantee.
	Lowest.	Highest.	Average.	Lowest.	Highest.	Average.	
Nitrogen .....	0.40	8.78	2.09	0.30	8.08	2.23	0.14
Available phosphoric acid .....	1.93	11.00	7.63	.83	19.68	8.44	.81
Insoluble phosphoric acid .....				.10	8.06	2.19	
Potash .....	.14	19.00	4.30	.08	15.58	4.57	.27
Water-soluble nitrogen .....				.01	6.25	.95	
Water-soluble phosphoric acid .....				.20	12.47	4.97	

“In 293 brands of complete fertilizers the amount of nitrogen found was equal to or above the guaranteed amount, the excess varying from 0.01 to 2.73 per cent, and averaging 0.30 per cent. In 107 brands the nitrogen was below the guaranteed amount, the deficiency varying from 0.01 to 2.25 per cent and averaging 0.29 per cent. In 87 cases the deficiency was less than 0.5 per cent. . . .

“In 326 brands of complete fertilizers the amount of available phosphoric acid was above the amount guaranteed, the excess varying from 0.01 to 10.68 per cent and averaging 1.14 per cent. In 74 brands the available phosphoric acid was below the guaranteed amount, the deficiency varying from 0.01 to 3.06 per cent and averaging 0.58 per cent. In 49 cases the deficiency was below 0.5 per cent. . . .

“In 297 brands of complete fertilizers the amount of potash found was above the guaranteed amount, the excess varying from 0.01 to 4.41 per cent and averaging 0.53 per cent. In 103 brands the potash was below the guaranteed amount, the deficiency varying from 0.01 to 8.32 per cent and averaging 0.47 per cent. In 85 of these cases the deficiency was less than 0.5 per cent. In 88 cases among the 400 brands of complete fertilizers the potash was contained in the form of sulphate free from an excess of chlorids.

“The retail selling price of the complete fertilizers varied from \$15 to \$60 a ton and averaged \$28.92. The retail cost of the separate ingredients unmixed varied from \$1.80 to \$34.25 and averaged \$20.17, or \$8.75 less than the selling price.”

**Artificial fertilizers from apatite and similar mineral phosphates, G. E. BROMS** (*Ugeskr. Landm., 42 (1897), No. 32, p. 421*).—The process of treatment consists in fusing the mineral phosphate with sodium carbonate, when tetra calcium-sodium phosphate is formed. This is insoluble in water, but easily soluble in ammonium-citrate solution. The reaction which takes place is as follows:

The method has been patented in Sweden and Denmark, and patents have been applied for in other countries.—F. W. WOLL.

**Fertilizer experiments in Smaalenene, Norway,** F. H. WERENSKIOLD (*Norsk Landmansblad*, 1896, No. 32, pp. 377, 378).—The object of the experiments was to investigate the effect of lime on marsh and clay soils sown to oats. They were conducted on 7 different farms in Smaalenene district, Norway. The fertilizers applied were Thomas slag and nitrate of soda, with or without the addition of lime. The rather wet season, in connection with the (under the conditions) somewhat heavy application of nitrate of soda caused the oats to lodge on all farms. It was noticed that the oats on the limed plats lodged first, the lime evidently converting a portion of the nitrogen of the soil into available form, and thus acting like one-sided nitrogen fertilization.

The following table gives the average results for the 2 classes of soils as regards the yield and the chemical composition of the oats and oat straw produced.

*Average results of liming oats.*

	Character of soil.	Yield.	Composition.							
			Water.	Ash.	Fat.	Crude protein.	Crude fiber.	Nitrogen-free extract.	Digestible protein.	
Oats:		<i>Kg.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per ct.</i>	<i>Per cent.</i>	<i>Per cent.</i>

—F. W. WOLL.

Some of the principles which should determine compensation for the use of foods and manures, R. WARINGTON (*London: Vinton & Co., pp. 44*).—This is a discussion based largely upon experimental work at Rothamsted and Woburn on the amount which should be paid by an incoming tenant to an outgoing tenant for permanent improvements due to use of fertilizers and feeding stuffs on the farm as provided for in the Act of Parliament of 1883.

On the preservation of barnyard manure, C. VON FEELITZEN (*Landtmannen*, 8 (1897), No. 45, pp. 635-637).

On the manufacture of peat litter, P. HAUGAN (*Tidsskr. Norske Landbr.*, 4 (1897), No. 11, pp. 511-514).

Distributors of liquid manures, M. RINGELMANN (*Jour. Agr. Prat.*, 1 (1898), No. 5, p. 174).

"Natural plant food;" claims made for it and its value, B. W. KILGORE (*Mississippi Sta. Bul.* 43, p. 14).—Analyses of this material are reported which indicate that it is a "low-grade natural phosphate of too poor a quality to be used in the manufacture of acid phosphates or other fertilizers." Such a phosphate can be bought at the mines for from \$2 to \$3 per ton, while the price asked for the so-called "natural plant food" was \$11 to \$17 per ton.

**Analyses of commercial fertilizers**, M. A. SCOVELL, A. M. PETER, and H. E. CURTIS (*Kentucky Sta. Rpt. 1896*, pp. 83-96, 99-108).—A reprint of Bulletins 64 and 65 of the station (E. S. R., 8, pp. 300, 970).

**Analyses of commercial fertilizers**, B. W. KILGORE ET AL (*Mississippi Sta. Spec. Buls. 42*, pp. 15: 45, pp. 18).—These bulletins include statements regarding the fertilizer control in Mississippi, explanations of terms used in reporting analyses of fertilizers, notes on valuation of fertilizers, lists of brands licensed for sale in the State with guaranteed analyses, and tabulated analyses and valuations of 93 samples of fertilizing materials collected during the latter part of December, 1897, and January, 1898.

**Analyses of commercial fertilizers**, W. C. STUBBS (*Louisiana Stas. Bul. 49, 2. ser.*, pp. 163-198).—This bulletin gives the text of the State fertilizer law, discusses the nature and sources of the various fertilizing materials supplying nitrogen, phosphoric acid, and potash in fertilizers, and the valuation of fertilizers, gives a list of guaranteed analyses of fertilizers licensed for sale during the seasons of 1896 and 1897, and reports analyses of 171 samples of fertilizing materials, including ammoniated superphosphates and guanos, acid phosphates, cotton-seed meal, tankage, nitrate of soda, dried blood, bone, cotton-hull ashes, potassium sulphate, kainit, and "natural plant food."

Analyses of the last-named material "show beyond doubt that it is a natural phosphate, finely ground, mixed, perhaps with a small quantity of kainit."

**The agricultural value of phosphatic slag**, L. GRANDEAU (*Ann. Sci. Agron.*, 1897, II, No. 3, pp. 432-444).—A general discussion of this subject, devoted largely to the work of Wagner, Maercker, Meissl, and Petermann and Graftiau, but including also results of experiments by the author on beans, potatoes, and maize, which lead to the conclusion that there is no relation between the solubility of a phosphate in acid citrate solution and its assimilation by plants. The author, therefore, recommends that slag be bought on guaranty of total phosphoric acid and fine meal.

**American phosphates** (*L'Engrais*, 13 (1898), No. 8, pp. 180, 181).—A statement of shipments from different American ports in 1897.

**On the Russian phosphate deposits**, R. GRIPENBERG (*Biet*, 19 (1898), No. 1, pp. 10-12).

**The deposits of phosphate of lime in Algeria**, L. GRANDEAU (*Ann. Sci. Agron.*, 1897, II, No. 2, pp. 213-260).

**On the action of phosphoric acid in field experiments with Thomas slag and ground bone**, E. MEISSL and REITMAIR (*Ztschr. Landw. Versuchsw. Oesterr.*, 1 (1898), No. 1, pp. 78-88).

**Artificial fertilizers**. H. JUHLIN-DANNFELT (*K. Landt. Akad. Handl. Tidskr.*, 36 (1897), No. 4, pp. 203-235).

**A bill governing the sale of fertilizers, feeding stuffs, and seeds** (*Tidskr. Landtmän*, 18 (1897), No. 38, pp. 679-684).—The text of a bill introduced in the Swedish Parliament, with discussions of the same.

## FIELD CROPS.

**Second report on potato culture**, I. P. ROBERTS and L. A. CLINTON (*New York Cornell Sta. Bul. 110*, pp. 385-390, fig. 1).—This work is in continuation of experiments made in 1895 and 1896 (E. S. R., 9, p. 343). The results for the three years are given in tables.

The soil upon which the experiments were made contained about one-half the total amount of plant food carried by an average soil and in consequence the authors ascribe the satisfactory results obtained to the culture and treatment of the crop. The land was plowed April 2

and 3, as early as the conditions of the soil permitted, and between the time of plowing and planting the soil was brought to a superior condition of tilth and a soil mulch established by harrowing frequently. All plats were planted May 7. The rows were 40 in. apart and single pieces of seed were planted 14 in. apart in the row. Large marketable potatoes, free from scab and as perfect as could be obtained, were selected for seed, and the cuttings were made of good size, with 1 or 2 strong eyes to each cutting. The practice of using parings or single eyes or buds for seed and the use of small potatoes for the same purpose is discouraged.

The following table gives the results for this season:

*Yield of potato plats for 1897.*

No. of plat.	Variety.	Number of cultivations.	Number of sprayings with Bordeaux mixture and Paris green.	Total yield per acre.
34	Carman No. 3.....	8 level.....	4	<i>Bushels.</i> 384

In 1896 forage crops were grown on all the plats, except on plat 34, on which spurry was grown, the first and second crops being plowed under. After the second plowing the spurry reseeded again and was left as a cover crop. The large yield of this plat is credited to its better treatment. Plats 37 and 38 were treated alike, except that at the last cultivation plat 37 was left level and plat 38 was hilled. There was a difference in yield of 37 bu. per acre in favor of level culture.

"The general results with culture verify the results obtained in 1896, *i. e.*, that in the ordinary season about 7 to 9 cultivations with a fine-toothed implement are likely to give best results."

**Sugar beets in Michigan in 1897**, C. D. SMITH and R. C. KEDZIE (*Michigan Sta. Bul. 150, pp. 123-158, figs. 6, map 1*).—This bulletin gives reports of experiments with sugar beets at the station and of cooperative experiments made by farmers throughout the State. Results of numerous analyses are tabulated, notes on the soil and climatic conditions for sugar beets are given, and a number of varieties of beets are described. The mean weekly temperature and rainfall for the beet season is given in a table.

At the station plats of well-drained, sandy loam soil were plowed 8 in. deep on April 17, followed by a subsoil plow which loosened the soil from 8 to 10 in. below the furrow. After the soil had been brought to

a fine tilth, the beet seed was planted on May 8 in rows 22 in. apart. Cultivation was given with the Breed Weeder May 17, before the plants had appeared on the surface, and with 1-horse cultivators June 1, 12, and 21. At the time of the last cultivation the beets, then showing the fourth leaf, were thinned to 1 plant every 8 in. Corn had been grown on the plats the year before, and prior to that the land had been a meadow for 3 years.

The following table gives the results obtained:

*Yield of sugar beets.*

Variety.	Yield	Sugar	Coeffi- cient of purity.
	per acre.	content.	
	<i>Pounds.</i>	<i>Per cent.</i>	
Wohanka .....	23,615	15.22	86
Improved Kleinwanzlebener .....	25,678	16.40	91
Original Kleinwanzlebener .....	27,368	18.27	94
Government Kleinwanzlebener .....	25,648	17.78	94
La Plus Riche .....	29,205	18.78	92
Government Kleinwanzlebener .....	32,327	17.78	94
Hoerning Improved .....	24,500	15.20	89
Floto Improved .....	20,200	13.21	88
Kleinwanzlebener on muck .....		12.96	75

An acre of beets required the labor of a man and team for 36.15 hours, and of a man for 209.9 hours. The hand work in harvesting, which required 130.75 hours, was performed by boys at 8 cts. per hour. Hoeing and thinning required 79.15 hours, and was done by men at 12½ cts. per hour. The work of a man and team was reckoned at 25 cts. per hour. At this price the cost of growing an acre of beets is estimated at \$29.40.

From 64 counties in the State 493 samples were received, 465 of which had been grown on suitable soil and from proper seed. These showed an average sugar content in the beet of 16.4 per cent, with an average coefficient of purity of 84. The results obtained in the different counties are shown on a map. The yields are considered to have ranged from 12 to 18 tons per acre.

The fertilizer requirements of the sugar beet, the value of beet pulp as food for stock, and the requirements of a factory are briefly discussed. An act passed by the Michigan legislature for the encouragement of beet-sugar manufacture is given in the bulletin.

**Field experiments with wheat,** J. F. HICKMAN (*Ohio Sta. Bul. 82, pp. 213-235*).—The work consisted of a comparison of varieties and investigations of different methods of culture. The results are tabulated and discussed.

The relative merits of the red and white and the smooth and bearded varieties of wheat are discussed. The names of the white and the smooth wheats are given, all others considered in the bulletin being red or amber in color or bearded. The different names under which some of the varieties are believed to occur are given.

Eighty-four varieties of wheat were tested. Among 40 varieties

grown continuously for 4 years Red Fultz, Poole, Nigger, Geneva, Mealy, New Monarch, Democrat, Deitz, Egyptian, Rudy, Japanese, Early Ripe, American Bronze, Valley, and Tuscan Island gave a greater average yield than the nearest plat of Velvet Chaff, the variety grown as a standard of comparison. Of these varieties, Mealy averages 4.32 bu. and Red Fultz 3.19 bu. more per acre than the standard variety; the other varieties mentioned yielding less than 3 bu. per acre more. The author reports Mealy, Red Fultz, Nigger, Geneva, and New Monarch to have given the best results in a series of tests, and recommends Velvet Chaff for the black soils, and Poole, Mealy, Red Fultz, Nigger, Deitz, and Rudy for the higher, and especially the clay, soils. The Rudy and Nigger varieties are not considered to be adapted to thin or wet lands. Varieties of wheat brought from the Northwest were not very successful. There was no superiority of one class of wheat over another as shown by the average yield.

The experiments with different methods of culture are described in detail, and directions for treating the seed to prevent smut are given.

From these experiments the author draws the following conclusions:

“Three successive crops, grown under adverse conditions, show that the heavier the seeding, under such conditions, up to 10 pecks per acre, the better the yield.

“From experiments made up to date it is recommended to sow in southern Ohio during the last week of September and the first week of October, but in northern Ohio from ten days to two weeks earlier.

“Compacting the seed bed before drilling seems to be the better plan on the clay as well as on gravelly or more open soils.

“A single trial of cross drilling with the same quantity of seed did not give any higher yield than where it was drilled but one way.

“One trial of cross drilling, using 3 pecks one way and 5 the other, gave less bushels per acre than 6 pecks drilled one way.

“Top-dressing the wheat ground six weeks before seeding, added materially to the yield, above the same kind and amount of top-dressing applied one week before seeding.

“Ground manured during the winter direct from the stable for corn and another piece manured just before plowing in the spring gave higher yields of oats from the earlier application of manure and lower yields of wheat following the oats.

“Slightly higher yields of wheat have followed the disking corn ground for oats than where the ground was plowed for oats, but that difference was more than overcome by a higher yield of oats from the plowed ground, and the lighter work of plowing again in the fall.

“The degeneration from sowing seed not selected is remarkably slow and not absolutely determined by our experiments thus far.”

**The requirements to be fulfilled for producing a good malting barley, P. BOLIN** (*Landmannen*, 8 (1897), No. 4, pp. 564-569).

**Investigations on potash manuring in barley culture, T. REMY** (*Wehnscr. Brau.*, 14 (1897), Nos. 50-52, p. 610; *abs. in Chem. Ztg.*, 22 (1898), No. 9, *Repert.*, p. 20).—The conclusion is drawn that a liberal application of potash fertilizers on soils poor in that constituent increases the yield and enables the crop to more fully utilize the nitrogen present in the soil.

**Carrot culture, LILIENTHAL** (*Landw. Wehnbl. Schleswig-Holstein*, 48 (1898), No. 8, p. 141).—Directions for the culture of carrots with reference to soil, rotation, manuring, cultivation, harvesting, and their uses for feeding.

**The superiority of superphosphate on cereals in spring,** MAIZIÈRES (*L'Ingrais*, 13 (1898), No. 8, pp. 178-180, fig. 1).—A popular discussion of this subject.

## HORTICULTURE.

**Indoor lettuce culture,** W. STUART (*Indiana Sta. Bul.* 66, pp. 39-58, pls. 2, fig. 1).—A test of fertilizers in forcing lettuce is reported. The plants were grown in a black loam soil obtained from a plat of ground on which various crops had been grown without having received any fertilizers for a number of years. The plants were subwatered throughout the entire test. The bench, 19 ft. long by 3 ft. 9 in. wide, was divided into six sections. Various fertilizers were applied alone and in various combinations to the different sections, two sections receiving no fertilizer, one section muriate of potash, one muriate of potash and nitrate of soda, one muriate of potash and dissolved boneblack, and one muriate of potash, dissolved boneblack, and nitrate of soda. Muriate of potash was applied at the rate of 1,026 lbs. per acre, nitrate of soda and dissolved boneblack each at the rate of 1,503 lbs. per acre. The method of growing the plants and the amount of fertilizer applied to each section of the bench are given. Two crops were grown successively on the same soil with but one application of ferti-

lizers. The plants of the first crop were measured about a month after being set in the bed and were harvested and weighed twelve weeks after being set. Those of the second crop were measured four weeks and weighed ten weeks after being set in the bed. In the second crop no attempt was made to grow large heads, the plants being set very close together. The results are given in tables and illustrated by diagrams and figures from photographs. The following table gives the average height and weight of plants grown with the different fertilizers:

*Effect of large quantities of different fertilizers on forcing-house lettuce.*

Kind of fertilizer.	Average height of plants.		Average weight of plants.	
	First crop.	Second crop.	First crop.	Second crop.
	<i>Inches.</i>	<i>Inches.</i>	<i>Grams.</i>	<i>Grams.</i>
None .....	2.64	2.05	22.66	13.00
Muriate of potash .....	2.26	1.92	19.83	16.42
Muriate of potash and nitrate of soda .....	2.30	1.61	11.05	9.11
Muriate of potash and dissolved boneblack .....	3.35	3.82	79.60	30.89
Muriate of potash, nitrate of soda, and dissolved boneblack ..	3.34	2.95	82.29	44.71

The author gives the following summary of the experiment:

“The application in large quantities of muriate of potash to a soil having a moderate amount of phosphoric acid caused a large decrease in yield in the first crop and without additional fertilizers an increase in the second. The addition of both muriate of potash and nitrate of soda in excessive amounts caused a very large decrease in the first crop, with a less marked one in the second. Dissolved boneblack and muriate of potash when applied in excessive amounts gave a very marked increase in the first crop, with a considerably less marked one in the second. The application of all three fertilizers in excessive amounts gave a very large increase in the first crop, with almost as large a one in the second. The dissolved boneblack and muriate of potash gave the plant the quickest start, as in each crop the plants in that section were considerably larger than in the others. Phosphoric acid seems to be an essential factor in the growth of lettuce.”

To discover whether the percentages of moisture and ash in the plants had any relation to the weight of the plants or to the fertilizers used, determinations were made of the moisture and ash of mature plants from the first crop. The results of the determinations are given in the following table:

*Relation of fertilizers and yield to percentages of ash and moisture content of lettuce.*

Kind of fertilizer.	Average weight of plants.		Ash.
	<i>Grams.</i>	<i>Per cent.</i>	<i>Per cent.</i>
None .....	22.66	96.22	21.72
Muriate of potash .....	19.83	96.35	23.86
Muriate of potash and nitrate of soda .....	11.05	95.34	22.54
Muriate of potash and dissolved boneblack .....	79.60	97.63	24.19
Muriate of potash, nitrate of soda, and dissolved boneblack .....	82.29	98.18	24.37

Two tests were made to determine the effect of forcing lettuce in pots. In the first test Grand Rapids and White Seeded Tennisball lettuce were grown. Two weeks after the seed was sown the young

plants that were to be grown in pots were transplanted into 2½ in. pots, and those that were to be grown in the open were transplanted into flats. Between 2 and 3 weeks later the plants were set in a bed, where they remained about 10 weeks. At the time of transplanting into the bed the White Seeded Tennisball plants grown in flats were about 26 per cent higher than those grown in pots, and the Grand Rapids plants grown in flats about 13 per cent higher than those grown in pots. At the time of harvesting the crop the average weight of the White Seeded Tennisball plants grown without pots was 60.32 gm., and that of the ones grown in pots was 48.76 gm. The Grand Rapids plants grown without pots averaged 154.8 gm. in weight and those grown in pots averaged 107.22 gm. In the second test Grand Rapids lettuce was used alone. Instead of transplanting part of the young seedlings into flats, as was done in the previous test, all of them were potted. When placed in the permanent bed, part of the plants were removed from pots and the others were plunged in soil with the pots, as in the first crop. The two lots of plants were of equal size when set in the bed. The plants remained in the bed about seven weeks. When harvested the plants grown without pots had an average weight of 203.03 gm.; those grown with pots an average weight of 150.6 gm.

A test was made to determine whether lettuce plants when set 8 in. apart yield as much in weight per square foot as when set 6 in. apart.

"The result of this comparative test was very much in favor of the close planting, a yield of 567 gm. per square foot being obtained from those set 6 in. apart as against 313 gm. from those 8 in. apart, making a gain in favor of the former of over 80 per cent. It should be said, however, that the plants were marketed when those set 6 in. apart were commencing to crowd each other for space, hence those set 8 in. apart had not grown as large as they probably would have done if allowed to remain longer."

To test a supposition that lettuce plants lose weight by "bleeding" when cut from the roots in marketing, some plants were cut off even with the soil and others were pulled up. The plants were weighed, washed, prepared for market, and left in a warm room for 6 hours, when they were again weighed. As to results the author says:

"The only indication given by this experiment is that it matters little which method is practiced, especially if the plants are sufficiently mature, when probably little bleeding occurs."

The history of subwatering in greenhouses is briefly given. For three years the station tested a method of subwatering by means of drain tiles cemented together and laid in the bottom of a water-tight bench. The method was abandoned on account of the uneven distribution of water throughout the bed. A method adopted by the station is described. It is a modification of the one reported by the Wisconsin Station (E. S. R., 9, p. 557). A zinc pan 3 or 4 in. deep is fitted in the bottom of the bench and a layer of soft brick set edgewise in it to conduct the water to the soil above. The water is admitted by means of vertical tubes extending to the bottom of the pan. The lower edges of the bricks are chipped off to form channels for the freer distribution

of water in the pan. At first the pan was provided with two overflows  $1\frac{1}{2}$  in. above the bottom. Later water gauges were put in, so that the height of the water in the pan could be seen at any time. The method was found to be a very efficient means of distributing the water evenly. The expense of fitting a bench with this system of subwatering was 13 cts. per square foot. The author believes this additional outlay is more than counterbalanced by the increased yield, the lessened labor in attendance, and the greater durability of the bench.

**Forcing tomatoes—comparison of methods of training and benching,** S. A. BEACH (*New York State Sta. Bul. 125, pp. 275-304, figs. 3, pls. 6*).—The bulletin reports tests of different methods of benching and training tomatoes in forcing houses. Two tests were made in the winter of 1895-'96 and three in the winter of 1896-'97. In all the tests Lorillard tomatoes were used. All plants in each test were grown from the same lot of seed and were selected to give specimens as uniform as possible. Soils and fertilizers were uniform for all plants in each test, and other conditions, except the ones to be compared, were as nearly alike as possible. The seeds were germinated in flats and the seedlings transplanted into small pots,  $2\frac{1}{2}$ -in. pots in the first two tests and 2-in. pots in the third test. When set in the benches a part of the plants were removed from the pots and part were left in them, the soil being mounded up above the pots to the seed leaves of the plant. Part of the plants in pots and part of those not in pots were trained to single stems, and part of each were trained to three stems. Each single stem plant was allowed only half as much bench room as each three-stem plant, the areas in the different tests being  $2\frac{1}{8}$ ,  $2\frac{3}{8}$ , and  $2\frac{5}{8}$  sq. ft. for the former and  $4\frac{1}{4}$ ,  $4\frac{3}{8}$ , and  $5\frac{3}{8}$  sq. ft. for the latter.

A summary of the data secured in these tests is given in the following table:

*Results of experiments with tomatoes.*

Method of growing plants.	Number of plants.	Average time from seed planting to first ripe fruit.	Average number of fruits per plant.	Average weight of individual fruits.	Yield per square foot of bench.
<i>First test.</i>					
In pots:		<i>Days.</i>		<i>Ounces.</i>	<i>Ounces.</i>
Single-stem training.....	33	160.15	15.97	1.76	13.21
Three-stem training.....	17	159.17	24.94	2.04	11.74
Not in pots:					
Single-stem training.....	31	157.90	13.60	2.00	12.79
Three-stem training.....	17	160.15	25.35	1.93	11.52
<i>Second test.</i>					
In pots:					
Single-stem training.....	7	102.57	18.43	2.66	20.37
Three-stem training.....	6	96.00	27.83	2.72	15.96
Not in pots:					
Single-stem training.....	9	99.78	16.56	2.82	19.68
Three-stem training.....	7	97.00	27.86	2.79	16.37
<i>Third test.</i>					
In pots:					
Single-stem training.....	18	173.78	23.17	2.84	23.20
Three-stem training.....	9	168.89	37.11	2.45	16.04
Not in pots:					
Single-stem training.....	20	172.45	25.15	2.77	24.56
Three-stem training.....	10	171.30	44.40	2.49	19.53

Although the first fruits as a rule ripened somewhat earlier on the plants trained to three stems than on those trained to single stems, yet the amount of fruit ripened early in the test was greater in case of the single-stem plants than of the three-stem ones.

The author gives the following conclusions:

"Single-stem training is clearly superior to three-stem training for forcing tomatoes in winter in this climate. The superiority is seen in the larger yield of early ripening fruit and in the larger total yield. There is but slight difference in the average size of fruit produced under the two methods of training, but on the whole the fruit of the single-stem plants seems to be slightly the larger.

"Plants in 2 or 2½ in. pots plunged in the soil so that roots may be formed above the pot as compared with similar plants knocked out of the pots and planted in the soil on the bench sometimes show slight gain in yield when plants are trained to single stem, but this treatment is a disadvantage when plants are trained to three stems."

**Variety tests with raspberries, blackberries, and dewberries,** W. PADDOCK (*New York State Sta. Bul. 128, pp. 339-349*).—The results of the variety tests are recorded in tables, showing such data as yield, dates of first and last picking, percentage of early and late yield, etc. The test included 11 varieties of black raspberries, 22 of red raspberries, 7 of purple blackberries, 19 of blackberries, and 4 of dewberries. Descriptive notes are given on some of the newer varieties. The results of the tests are summarized as follows:

"Poscharsky No. 15 takes first rank among black raspberries, both as to total yield and the amount of fruit produced early in the season. Palmer has a long season, as it is classed with both early and late berries. Babcock No. 5 and Mills were the two most productive late berries.

"Of red raspberries, Pomona gave the largest early yield and ranks second in productiveness. Cline ripens most of the crop in a few days, and, as is usual with very early berries, is unproductive. Kenyon and Olathe were the most satisfactory late red raspberries. Of the mid-season varieties, Loudon, Guthbert, and King deserve special mention.

"Shaffer and Columbian are as yet the two standard varieties of purple raspberries.

"Of blackberries, Dorchester, Success, New Rochelle, and Stone Hardy were the most productive in 1897. Dorchester and New Rochelle have not always been hardy here. Early King produced the largest early yield.

"Lucretia is as yet the only dewberry of importance in this section."

**Strawberries in 1897,** W. PADDOCK (*New York State Sta. Bul. 127, pp. 327-338*).—The bulletin reports a variety test of strawberries. A table is given showing the yield of 28 varieties of strawberries in one-year-old beds, with a comparative statement of the early and late yield of each variety. A second table compares the early varieties, and a third table the late varieties. In a similar way the bulletin records the data obtained from the test of 28 varieties grown in two-year-old beds. Descriptive notes are given on 26 of the newer varieties of strawberries. The following summary is given:

"Of strawberries in one-year beds Beder Wood was the most productive early berry. It is also a satisfactory general-purpose variety, as it took second rank as to yield among the kinds that were fruited in one-year beds. Marshall is worthy of a trial for fancy fruit. Glen Mary was the most productive berry and produced the

largest late yield. None of the strawberries in two-year beds succeeded more than moderately well, owing, no doubt, to winter injury and an unfavorable growing season. Earliest produced the largest early yield, while Robinson was the most productive and gave the largest late yield."

**Strawberries**, L. R. TAFT and H. P. GLADDEN (*Michigan Sta. Bul.* 148, pp. 51-63).—Data obtained from the test of 90 varieties of strawberries are recorded in tables, showing the size, form, color, quality, and firmness of fruit; dates of bloom and of first and last fruits; and sex and vigor of plants. Descriptive notes are given on 42 varieties fruited for the first time at the station in 1897, and on 54 new varieties of 1896. The following are recommended: Varieties for the market grower—Bubach, Crescent, Haverland, Warfield, Parker Earle, Beder Wood, Sharpless, Clyde, Woolverton, Bird, Charlie, Greenville, Leroy, Snowball, and Weston; large-fruited varieties—Brandywine and Marshall; late varieties—Aroma and Eureka; varieties for home use—Brunette and Timbrell. Of the newer sorts the following are the most promising: Enormous, Kansas, Mary, Meridian, Ona, Sherman, and Thompson 103.

**Subwatering**, F. CRANFIELD (*Amer. Florist*, 13 (1898), No. 512, p. 374).—Notes on methods of subwatering in greenhouses. The author states that it is not necessary to have the benches absolutely level in order to use successfully the brick method employed at the Wisconsin Station (E. S. R., 9, p. 557). A disadvantage of the tile method is that the water is not uniformly distributed.

**Subwatering**, W. J. GREEN (*Florists' Exchange*, 10 (1898), No. 13, p. 341, fig. 1).—The advantages claimed for subwatering of carnations are the thoroughness of watering, the saving of time in watering, and the production of better flowers and longer, stiffer stems.

**Further notes on subwatering**, J. C. ARTHUR (*Amer. Florist*, 13 (1898), No. 513, p. 384).

**Application of heat to greenhouses**, W. R. BEATTIE (*Florists' Exchange*, 10 (1898), No. 13, pp. 314, 315, fig. 1).—The article is reprinted from the *Columbus Horticultural Journal*.

**Suitable fertilizers for fruit** (*Florida Farmer and Fruit Grower*, 10 (1898), No. 14, pp. 211, 212).

**The cultivation of American ginseng in Pennsylvania**, G. C. BUTZ (*Pennsylvania Dept. Agr. Bul.* 27, pp. 23, pls. 3, figs. 4).—A popular bulletin on the culture and uses of ginseng.

**Asparagus culture**, P. CHERVIN (*Bul. Div. Agr. et Com.*, 3 (1898), No. 6, pp. 57-62).

**Fertilizers for lettuce** (*Amer. Gard.*, 19 (1898), No. 161, Sup. pp. VI-VIII, figs. 3).—This paper consists of extracts from Bulletin 66 of the Indiana Station (see p. 1048).

**Fruit culture in Denmark and Sweden**, I. ILSENG (*Tidsskr. Norske Landbr.*, 4 (1898), No. 12, pp. 544-551).

**Seedling apples** (*Gard. Chron.*, 3. ser., 23 (1898), No. 585, pp. 145, 146).—A discussion of the improvement of varieties of apples by crossing.

**The plum**, A. H. PEARSON (*Garden*, 53 (1898), No. 1375, pp. 263-266).—A paper read before the Royal Horticultural Society (England), discussing culture and varieties of plums.

**Third report upon Japanese plums**, L. H. BAILEY (*New York Cornell Sta. Bul.* 139, pp. 369-382, figs. 9).—Notes are given on those varieties of Japanese plums that

fructed at the station during the season of 1897. In regard to the merits of the Japanese plums the author says:

"I am still convinced that the Japanese plums have come to stay. By this I do not mean that they are destined to supplant the domestic and native plums, but that they are bound to supplement those types with varieties that are adapted to particular purposes and conditions. As a class they are vigorous, hardy, and productive in tree, and the fruit is handsome, long keeping, and covers a long season. Thus far they have been comparatively free from black knot, and until this year our trees have not been seriously attacked by the shot hole fungus or leaf blight. During the past season, however, this leaf blight has been much worse upon the Japanese varieties than upon the domestics alongside them, and this, too, in spite of the fact that they were thoroughly sprayed. The leaves did not drop to any extent, however, even though they were badly riddled by the fungus."

**Analyses of pomegranates**, A. BORTRAGER and G. PARIS (*Ztschr. Untersuch. Nahr. u. Genussmtl.*, 1898, No. 3, pp. 158-163).—An extended study of the pomegranate, including composition of seed and juice, fresh and fermented. The authors do not think that Italian pomegranates are suitable for wine making on account of their low sugar content.

**Strawberries, new and old**, C. W. MATTHEWS (*Kentucky Sta. Rpt. 1896*, pp. 45-57).—A reprint of Bulletin 62 of the station (E. S. R., 8, p. 231).

**Culture of hazelnut trees for fruit**, P. MOUILLEFERT (*Prog. Agr. et. Vit.*, 29 (1898), No. 9, pp. 272-279, figs. 3).

**New Italian cannas**, E. ANDRE (*Rev. Hort.*, 70 (1898), No. 5, pp. 108-110, pl. 1).

**The cyclamen**, D. GUIHENEUB (*Garden*, 53 (1898), No. 1373, pp. 210-213).—A discussion of the classification and culture of the cyclamen.

**Crown and terminal buds of chrysanthemums**, W. MILLER (*Florists' Exchange*, 10 (1898), No. 13, pp. 325, 327, 329, figs. 4).—A discussion of the choice of flower buds of chrysanthemums to secure flowers for exhibition.

**Ornamental bedding**, H. HANSEN *Amer. Florist*, 13 (1898), Nos. 511, pp. 913, 914; 512, p. 946; 513, p. 994, figs. 12).

**Orchards for commercial culture**, R. M. GREY (*Florists' Exchange*, 10 (1898), No. 13, pp. 329, 331).

**Report of the horticultural department of the experiment station at Albano, Sweden, 1897**, E. LINDGREN (*K. Landt. Akad. Handl. Tidskr.*, 36 (1897), No. 4, pp. 257-265).

## SEEDS—WEEDS.

**First Ohio weed manual**, A. D. SELBY (*Ohio Sta. Bul.* 83, pp. 248-400, figs. 71).—In the preliminary part of the bulletin the author discusses the nature of weeds, methods of introduction and spread, the vitality of weed seeds, principal methods of weed destruction, and legislation needed for weed suppression. A descriptive illustrated list of various weeds arranged in sequence of families is given. The author discusses the occurrence of weed seeds as impurities of grass and other seeds, and calls attention to the necessity of seed inspection. Twenty-nine species of weed seed are reported as having been found in clover seed during the past three years, and seven species of weed seed were found in timothy seed offered for sale. The bulletin concludes with lists of roadside weeds compiled from information received in response to a request in Bulletin 59 of the station (E. S. R., 7, p. 690), the intention being to show the relative importance of the different roadside weeds.

**On the destruction of wild mustard** (*Bul. Sta. Agron. Laon, 1897, pp. 68, 69*).—The announcement of Bonnet that a solution of copper sulphate would destroy wild mustard and wild radish when growing among cereals without injury to the latter was tested at the station. It was found that 5 per cent solutions at the rate of 800 to 1,000 liters per hectare sprayed over grain fields early in the year destroyed the wild mustard but was without effect upon the wild radish and other weeds, although the plants were quite young. Evidently this strength of solution was not sufficient for the destruction of wild radish, etc. The leaves of the grain were slightly injured, but quickly recovered. No effect was noticed on alfalfa or clover sown with the cereal. A 15 per cent solution of iron sulphate may be substituted for the copper sulphate where it would be cheaper, but the 5 per cent copper solution is preferred. The cost of treatment where power spraying machines are used is given at approximately \$2 per acre.

**On the seeds and testa of some Cruciferæ**, L. H. PAMMEL (*Amer. Mo. Micros. Jour., 18 (1897), Nos. 7, pp. 205-210; 9, pp. 269-274; 10, pp. 312-317, pls. 5*).—Notes are given on the seeds of *Brassica nigra*, *B. sinapistrum*, *B. alba*, *Sisymbrium officinale*, *S. altissimum*, *Lepidium virginicum*, *L. apetalum*, *Capsella bursa pastoris*, *Barbarea vulgaris*, and *Camelina sativa*.

**Researches on germination**, V. JODIN (*Ann. Agron., 23 (1897), No. 10, pp. 433-471*).—Notes are given on the latent life of seeds, their hydration, their chemical inactivity during the resting period, minimum amount of water necessary for the respiration of seeds, influence of an excessive proportion of carbon dioxide on germination, and minimum quantity and state of oxygen necessary for germination.

**Concerning a considerable source of error in testing clover seed**, M. GLOCKEN-TOEGER (*Landw. Vers. Stat., 49 (1897), No. 3, pp. 219-222, figs. 10*).—The author reports upon a possible source of error in testing clover seed, especially when tested in sand or soil seed beds, and shows that broken seed coats or malformations of the seedling may result in the nonappearance of from 0 to 46 per cent of the plants above the surface of the soil. The author reports upon 113 experiments and comments on the nature of the different seedlings as a result of injury.

**Concerning the methods of seed testing**, H. RODEWALD (*Landw. Vers. Stat., 49 (1897), No. 4-5, pp. 257-286, fig. 1*).—The principal part of this paper is taken up in the theoretical consideration of errors in seed testing and the discussion of formulas for the establishment of the limits of error. Experimental data are cited to prove the theoretical formulas. A form of seed-testing apparatus is figured and described in which the seed are germinated in porous cups. The temperature and moisture regulations are said to be under perfect control. Comments on the paper are made by J. C. Kapteyn.

**Report of seed control station at Christiania, Norway, for 1896**, B. LARSEN (*Christiania, 1897, pp. 8*).

**Report of seed control station at Gothenburg, Sweden, July 1, 1896 to June 30, 1897**, J. E. ALÉN (*Gothenburg, 1898, pp. 16*).

**Notes on introduced weeds**, J. B. DAVY (*Erythea, 6 (1898), No. 3, p. 26*).—The presence of *Centaurea solstitialis* and *Taraxacum officinale* as weeds is mentioned.

**Bermuda grass in Arizona**, J. B. DAVY (*Erythea, 6 (1898), No. 3, pp. 24, 25*).—Reports the Bermuda grass (*Cynodon dactylon*) as becoming troublesome in orchards, the seeds and rhizomes being distributed by irrigation ditches. The same is also true of Johnson grass (*Andropogon sorghum halepensis*).

**Cuscuta and its destruction**, G. HEUZÉ (*Jour. Soc. Agr. Brabant-Hainaut, 1898, No. 1*).

## DISEASES OF PLANTS.

**A bacterial disease of sweet corn**, F. C. STEWART (*New York State Sta. Bul. 130, pp. 423-439, pls. 4*).—The author describes a disease which has been under observation for the past three years and which has caused considerable damage to sweet corn in the market gardens of Long Island. Certain varieties seem to be more subject to the attack than others, and losses of 20 to 40 per cent, and even of the entire crop, are reported. The affected plants wilt and dry up without any apparent cause, and this may take place at any stage during their growth, but is most liable to occur about the time of flowering. The leaves first wilt and then gradually wither. The time which elapses between the appearance of the disease and the death of the plant varies greatly. Sometimes the plants recover, or may seem to recover for a time, and later yield to the disease. Nothing abnormal appears about the roots or subterranean portions of the stem except where the plants have been dead for a considerable time. The most distinct character of the disease is revealed when the stem is cut lengthwise, when the fibrovascular bundles appear as yellow streaks in the white parenchyma. If the stem is cut crosswise and the cut surface exposed to the air for a few moments a yellow, viscid substance exudes in drops. Examination of this substance revealed the presence of large numbers of bacteria, and it is to them that the disease is due. Pure cultures of the germ are easily obtained, the organism growing readily at temperatures of 21 to 28° C. in neutral media of beef agar, potato agar, and gelatin.

The organism is a short bacillus with rounded ends, usually occurring in pairs, with a plain constriction between the members. No spores have been observed, but old cultures have not been carefully examined and the absence of spores can not be definitely stated. The organism is motile, but not actively so. Its behavior on various culture media and its chemical, temperature, and light reactions are described.

The bacteria are always found in the vascular system, never occurring in the parenchyma cells, and they injure the vitality of the plant by plugging up the main water canals.

The identity of the bacillus is not fully established, but it is considered specifically different from that causing the disease of corn known as Burrill's disease, due to *Bacillus cloacæ*.

Inoculation experiments are reported in which it appeared that the soil or the seed may be sources of infection. Popcorn, field corn, oats, and teosinte proved not susceptible to the disease when subjected to soil and puncture inoculations. The author believes that the chief method of dissemination of the germ is through diseased seed. Another common way in which the germ is probably disseminated is by the use of manure from animals fed on the diseased stalks.

Soil treatments with lime and sulphur have proved of no benefit in preventing this disease. As far as practicable the planting of non-

susceptible varieties is recommended. The only other locality besides Long Island where this disease is known definitely to occur is Iowa, although it is probably of wide dissemination.

**Notes on *Ophibolus graminis*** (*Bul. Sta. Agron. Laon, 1897, pp. 63-66*).—This fungus attacks cereals between the ground and the first node, weakening the stem and causing it to fall over. The disease, which is known as black foot of wheat, has been rather severe in its attack. It is not confined to wheat, but rye and barley are also subject to its attack. A mild, moist winter is most favorable to the development of the fungus. The seed grain and chaff are said to be active agents in disseminating the disease, and treatment of the seed is of some value. However, attacks may follow the presence of the spores in the soil, etc.

Spraying with copper solutions are beneficial, or the dry powder, mixed with some chemical fertilizer, may be sown broadcast with good results. Experiments are to be conducted along this line, the application of copper being made with nitrate of soda and superphosphate in February. The estimated additional cost of such treatment for the disease is about 40 cts. per acre.

**Smut and bunt**, F. MADDIX (*Agr. Expts. Eastfield, Tasmania, 1897, pp. 72-81, figs. 3*).—The author gives the details of six years' experiments with smut and bunt of cereals. The experiments with bunt showed that it could be readily prevented by the use of different solutions of chemicals or by the hot-water treatment, but no method was learned for the prevention of the smut. He found in inoculation studies of the smut that the only means of securing infected grain was by putting spores on the ovary of the plant at the time of shedding the pollen by the flowers. Numerous experiments are reported in which no failures were secured if the smut spores were placed on the ovary at the proper time. It was found also that the period of ripening of the smut spores and that for the infection of the young grain closely corresponded. Numerous experiments were conducted by which it was sought to artificially produce disease on wheat, oats, and barley by inoculating them with spores of the smuts of wheat, oats, and grass, and wheat and barley bunt. The results of his inoculations are shown in tables. In no case were oat diseases conveyed to other plants, nor were they ever artificially induced on the oat plant. Successful inoculations were secured with the other plants.

**A bacterial disease of the grape (La maladie d'Oleron)**, L. RAVAZ (*Ann. École Nat. Agr. Montpellier, 9 (1895-96), pp. 298-317, pl. 1, figs. 14*).—Under the name of "La maladie d'Oleron," the author describes a disease of grapes which has been known for some time on the island from whence it takes its name. Lately the disease has been recognized in the vineyards of Charentes, Drome, and along the Mediterranean region. The disease is said to be of bacterial origin and to be readily communicated to unaffected vines. Its effect on the differ-

ent parts of the plant is described. No part of the plant is free from attack, although the roots are the last to be invaded. The vessels of the diseased wood are often found crowded with short motile bacteria. These organisms are said to be easily isolated, are aerobic, and grow readily on gelatin or in Liebig's bouillon to which glucose is added. The bacteria are slightly larger in cultures than in the diseased tissues, are 1.5 to 2.5  $\mu$  with an average of about 2  $\mu$  in length, are somewhat dumb-bell shaped and are readily stained.

Inoculations made upon sound shoots readily induced the disease, and where the bacteria were introduced in considerable quantity the diseased condition was quickly recognizable.

Experiments for the prevention of the disease are reported in which iron sulphate and copper sulphate were compared, and it appeared that washing the vines with a 20 per cent solution of copper sulphate aided in preventing attacks of the disease.

The relation of this disease to other diseases of the vine which are considered to be of bacterial origin is discussed.

**Description of *Bacillus phaseoli*, with some remarks on related species**, E. F. SMITH (*Proc. Amer. Assoc. Adv. Sci.*, 46 (1897), pp. 288-290).—An abstract is given of a paper read by the author at the Detroit meeting of the American Association for the Advancement of Science, August, 1897. The organism is described as follows:

"*Bacillus phaseoli*, n. sp., a short rod with rounded ends, yellow on various media, motile in early stages of growth, decidedly pathogenic to beans and some related legumes, and closely related to *Pseudomonas hyacinthi* and *P. campestris*. Its thermal death point is approximately 49° C., and it will not grow in the closed end of fermentation tubes in beef broth or peptone water with any of the ordinary sugars. It exerts a powerful diastatic action on potato starch. On bean pods it causes water-soaked spreading spots."

The organism has been under observation for more than a year and its parasitic nature unquestionably determined. The author presents the points of agreement and difference in tables so as to show the characterization of each of the above organisms.

**Note on a tomato disease**, S. A. BEACH (*New York State Sta. Bul.* 125, pp. 305, 306, pl. 1).—Descriptive notes are given by F. C. Stewart on a peculiar disease of tomatoes which was first noted in the forcing houses of the station. The disease has the general characters of the so-called black rot of tomato due to *Macrosporium tomato*, but examination revealed the total absence of fungus hyphae in the tissues in the earlier stages of the disease, and at no time are there abundant bacteria in the diseased fruits.

In general the disease begins as a slightly depressed circular brown spot, which gradually enlarges, retaining its circular form, until it frequently covers half the surface of the fruit. Most frequently the spot originates at the blossom end, but it may originate at any point on the fruit. The spots are first brown in color, later becoming brownish

black or greenish black, and are surrounded by light brown rings. The boundary line between the healthy and diseased tissue is conspicuously marked. The tissues within are blackened to a considerable distance below the surface and there is somewhat less than the normal amount of moisture present. There are no indications that either the stem or the leaves are attacked by the disease. Old specimens often show species of *Fusarium*, *Penicillium*, and various bacteria, but attempts made to cultivate in Petri dishes an organism from the diseased tissue developed nothing. If any organism is connected with this disease, it is one which does not readily grow in agar.

**Investigations concerning potato scab**, FRANK and KRÜGER (*Ztschr. Spiritusind.*, 19 (1896), *Ergänzungsheft*, pp. 9, pl. 1; *abs. in Bot. Centbl.*, 73 (1898), No. 9, pp. 327, 328).—The authors have made a study of the various forms of potato scab and some of the means for their prevention.

It is claimed that *Spongospora solani*, a rather common north European fungus, was not a constant accompaniment of the disease. Bolley's potato scab bacterium was not observed in any specimens. Thaxter's fungus, *Oöspora scabies*, was found abundantly. The authors are somewhat inclined to think the micro-organisms play a secondary rôle in the disease, the primary cause probably being some soil or other condition rendering the tuber susceptible of infection. Marling alone is said not to be the cause of this probable soil condition and the exact rôle played by marl is to be investigated further.

As preventive treatment the authors recommend soaking seed tubers in a 2 per cent Bordeaux mixture before planting.

**A lily bulb disease**, G. A. MASSEE (*Kew Misc. Bul.* 122-123, pp. 87-90, pl. 1).—This disease, brief mention of which has been given elsewhere (*E. S. R.*, 9, p. 457, is caused by a parasitic fungus, *Rhizopus necans*, illustrated descriptions of which are here given. It was first noticed on bulbs of *Lilium speciosum* and *L. auratum* from Japan. The fungus grows readily as a saprophyte in quite a number of culture media, fruiting in five or six days.

Culture experiments indicate that the fungus can not penetrate unbroken tissues and that it gains entrance to the bulbs through broken roots. It seems probable that the bulbs were not diseased when removed from the ground. A short immersion in a 1 per cent solution of salicylic acid or corrosive sublimate will destroy all spores on the bulbs. Onion bulbs are not subject to attacks of this fungus, but daffodils are, and it is said to have quite a range of dead and living hosts in Japan.

Precautionary measures, such as rotation of crops, avoidance of injury to roots, destruction of refuse, etc., are recommended for the prevention of the disease. When exported the bulbs should first be dipped into a solution of salicylic acid. They should also be allowed to thoroughly sweat before shipment.

**Results of oat smut in 1897,** C. P. CLOSE (*New York State Sta. Bul. 131, pp. 411-451*).—The author reports upon a series of experiments conducted for the prevention of oat smut. The methods tested were treatment of the seed with solutions of Ceres powder, lysol, formalin, potassium sulphid, and the Jensen hot-water treatment. Popular descriptions are given of the oat smut and methods of infection. The results of the different tests are tabulated and the cost of materials given. The hot-water treatment kept the crop wholly free from smut and none of the treatments injured the seed. Both sprinkling the seed with solutions and soaking them were tested. It was found that sprinkling the seed with a 1 per cent solution of either lysol or formalin entirely prevented the smut. The use of potassium sulphid did not entirely prevent smut attacks, and Ceres powder was found less effective. The results obtained by soaking the seed were similar to those just given. The cost per bushel of soaking the seed in a 0.3 per cent solution of lysol is about 2.7 cts.; in a 0.2 per cent solution of formalin, 1.4 cts.; in a 2 per cent solution of potassium sulphid, 5.4 cts., and in a 4 per cent solution of Ceres powder, 39.6 cts. The cost of the chemicals where the seed is sprinkled is 5 cts. per bu. for lysol, and 4 cts. for formalin, a 1 per cent solution being used in each case. Weaker solutions were not tried, but it is thought they may prove effective in preventing the smut.

**Conclusions of the Official Black Rot Commission,** L. DEGRULLY (*Prog. Agr. et Vit., 28 (1897), No. 47, p. 590*).—The commission appointed by the Government of France to investigate the subject of black rot, at its meeting at Bordeaux on November 19, announced the following conclusion:

The experiments conducted during the summer of 1897 showed the efficiency of copper solutions for the prevention of black rot. Of the solutions tested Bordeaux mixture containing not less than 2 per cent copper sulphate gave the best results.

The first application should be made when the young shoots are from 10 to 15 cm. long. The efficiency of subsequent sprayings depends upon the time of their application. The vines should be sprayed before the different periods of attack, which, in Armagnac, in 1897, occurred May 18, June 7, and July 6 and 25. For the ordinary attack of black rot four or five sprayings will be sufficient. The removal of diseased leaves is recommended, and in the autumn all diseased tissues should be collected and burned.

**Potato blights,** I. P. ROBERTS and L. A. CLINTON (*New York Cornell Sta. Bul. 140, pp. 392-406, figs. 3*).—The early and late blights of potatoes are figured and popularly described. A report is given of spraying experiments, in which 3 applications of Bordeaux mixture and Paris green and one of Bordeaux mixture alone were given a number of plats of potatoes, and the average total yield of the sprayed plats was 337 bu., as compared with 234 bu. in the check plat. In the course

of the experiments it appeared that different varieties of potatoes withstand attacks of these fungi to different degrees, Carman No. 3 being one of the most resistant, while Rose of Sharon was exceedingly susceptible to disease. Details are given for the preparation and application of the fungicides.

**Spraying in 1897 to prevent gooseberry mildew, C. P. CLOSE** (*New York State Sta. Bul.* 133, pp. 489-500, *dgm.* 1).—During the season of 1897 potassium sulphid, Bordeaux mixture, lysol, and formalin were tested side by side to determine their value for the prevention of the gooseberry mildew. The fungicides were applied at three different times, one lot receiving them just as the buds were opening, the second plats eleven days later, and the last sections twelve days after the applications to the previous sections. The first mildew appeared May 26 and by June 7 portions of the plantation were badly mildewed. At this time lysol and formalin seemed to have been without effect. Bordeaux mixture was more effective but not as good as potassium sulphid where the treatments were begun very early. The foliage was not injured by any of the fungicides. The cost of the solution of potassium sulphid, which gave the best results, was about 0.2 et. per bush for seven applications. The station recommends the use of potassium sulphid solution (1 oz. to 2 or 3 gal. water) as the most effective fungicide for the prevention of gooseberry mildew. The methods of application are given in detail and the results of the treatment are tabulated.

The general appearance of the fungus is described, and as a rule it was generally found that the English varieties and their seedlings are more subject to attack by mildew than the American varieties.

**Some aspects of vegetable pathology and the conditions which influence the dissemination of plant diseases, W. C. STURGIS** (*Bot. Gaz.*, 25 (1898), No. 3, pp. 187-194, *figs.* 5).

**Mycological notes, B. D. HALSTEAD** (*Bul. Torrey Bot. Club*, 25 (1898), pp. 158-162, *fig.* 1).—Notes are given on the hollyhock rust (*Puccinia malvaccarum*), wind as a means of spreading rust, relation between rainfall and potato rot, and the Phytophthora of Lima beans.

**Parasitic leaf fungi, A. S. WILSON** (*Amer. Mo. Micros. Jour.*, 18 (1897), No. 12, pp. 365-372, *fig.* 1).—Notes the occurrence and distribution of a number of the more common parasitic fungi.

**The bean anthracnose, B. D. HALSTED** (*Amer. Gard.*, 19 (1898), No. 169, p. 239, *figs.* 3).—Briefly describes anthracnose of bean due to *Colletotrichum lagenarium* and recommends the use of Bordeaux mixture for its prevention.

**Vegetable parasites of beets, H. BRIEM** (*Bl. Zuckerrübenbau*, 1897, Nos. 20, pp. 305-314; 21, pp. 321-331; 22, pp. 340-343).

**Concerning the winter forms of the cherry Monilia, FRANK and KRUGER** (*Gartenflora*, 47 (1898), No. 4, pp. 96-98).

**A disease of chestnuts in France, G. DELACROIX** (*Bul. Soc. Mycol. France*, 13 (1897), No. 4, p. 242).

**Concerning some fungus and insect enemies of coffee in Rio Janeiro, E. GOLDI** (*Arch. Mus. Nac. Rio de Janeiro*, 8 (1897), pp. 9-121, *pls.* 4).

**A probable cause of the so-called "malsania" of Corylus avellana, U. BRIZI** (*Centbl. Bakt. u. Par.*, 2. Abt., 4 (1898), No. 3-4, pp. 147-151).—This disease has been

usually attributed to attacks of fungi, several species of which are enumerated, but the author believes root galls cause considerable of the trouble. The origin of the galls is thought to be due to some small coleoptera.

**A new blastomycete parasitic on the fruit of the filbert, V. PEGLION** (*Atti R. Accad. Lincei*, 294 (1897), p. 276).

**A disease of pears, J. NORMANT** (*Monit. Fin.*, 1897, No. 95, p. 378).

**Concerning potato rots, E. ROZE** (*Compt. Rend. Acad. Sci. Paris*, 125 (1897), No. 25, pp. 1118-1120).—The author considers the potato rots under 2 divisions, the dry rots due to *Pseudococcis citis* and *Micrococcus* spp., and the wet rots due to *Micrococcus* sp. associated with *Bacillus subtilis* and to *Phytophthora infestans*.

**Insect and fungus pests of potatoes, H. GARMAN** (*Kentucky Sta. Rpt.* 1896, pp. 14-35, figs. 7).—A reprint from Bulletin 61 of the station (E. S. R., 8, p. 136).

**A bacterial disease of sweet corn, F. H. HALL** (*New York State Sta. Bul.* 130, popular ed., pp. 5, pls. 2).—A popular summary of Bulletin 130 of the station (see p. 1056).

**On rust on the small grains, J. SMITT** (*Tidsskr. Norske Landbr.*, 4 (1897), No. 10, pp. 441-445).—A résumé of J. Eriksson's results.

**A new disease of wheat in Sardinia, A. N. BERLESE** (*Bol. Not. Agr.*, 19 (1897), No. 13, pp. 430-437, figs. 2).—The author gives the life history of the fungus, *Sphaeroderma damnosum*, and an account of successful infection experiments. Ordinarily the fungus is saprophytic, but under some circumstances may become a destructive parasite.

**The wheat eel** (*Süchs. Landw. Ztschr.*, n. ser., 19 (1897), No. 34, pp. 480, 481, figs. 3).—This nematode (*Tylenchus Scandinus*), which is from 0.8 to 1 mm. long, is found in the kernels of matured wheat, where it produces what is called "rade korn," which is without the power of germination. The only remedy noted is the sifting out of the diseased kernels.

**An experiment with apple rot in 1896, H. GARMAN** (*Kentucky Sta. Rpt.* 1896, pp. XXXVII-XXXVI, pl. 1).—Notes are given on an experiment with Bordeaux mixture applied to Janet apple trees for the prevention of rot of the fruit. Two trees were selected, one being used as a check. Eight applications were made. The weight of sound apples from the sprayed tree when the fruit was gathered, September 26, was 62 lbs. 4 oz., while those from the unsprayed tree weighed 8 lbs. 6 oz. As the result of the treatment the total yield of sound apples was increased more than seven times.

**Results of experiments conducted in 1896 for the control of grape Peronospora, G. CUBONI** (*Bol. Not. Agr.*, 19 (1897), No. 12, pp. 401-411).—The results of experiments conducted in a large number of vineyards with various fungicides are reported. Bordeaux mixture, acetate of copper, sulphosteatite, copper-soda mixtures, copper sucrate, borol, etc., were tested with a view to securing some substitute for Bordeaux mixture. The results were negative in many cases and in others were very inferior to Bordeaux mixture. The experiments are to be repeated.

**Influence of fertilizers on the disease and injuries of grapevines, P. COSTE-FLORET** (*Prog. Agr. et Vit.*, 29 (1898), No. 10, pp. 300-308).

**On the use of corrosive sublimate against black rot, L. DEGRULLY** (*Prog. Agr. et Vit.*, 29 (1898), No. 12, pp. 353-355).—This fungicide is said to be as efficient as copper compounds for the prevention of black rot.

**On the preparation and use of bichlorid of mercury solutions as fungicides, L. DEGRULLY** (*Prog. Agr. et Vit.*, 29 (1898), No. 10, pp. 289-292).

**Best remedy for gooseberry mildew, F. H. HALL** (*New York State Sta. Bul.* 133, popular ed., pp. 6).—This is a popular summary of Bulletin 133 of the station (see p. 1061).

**Oat smut and new preventives, F. H. HALL** (*New York State Sta. Bul.* 131, popular ed., pp. 6).—This is a popular summary of Bulletin 131 of the station (see p. 1060).

**Formic aldehyde, G. L. TAYLOR** (*Amer. Jour. Pharm.*, 70 (1898), No. 4, pp. 195-201).—Notes are given on the preparation, analysis, and uses of this important germicide.

## ENTOMOLOGY.

**Food habits of North American Sesiidæ**, W. BEUTENMÜLLER (*Bul. Amer. Mus. Nat. Hist.*, 9 (1897), pp. 217-220).—The following food habits are noted: *Melittia satyriniiformis* lives in the roots and lower parts of the stems of squash vines and probably other allied plants; *M. gloriosa*, roots of sumac and the herbaceous climbing stems of *Megarhiza*; *Alcathöi caudatum*, roots of virgin's bower (*Clematis virginiana*); *Sannina uroceriformis*, roots of the persimmon; *Troehilium pacificum*, bores in the cottonwood and probably also the willow; *T. tibiale*, the trunks of poplar and willow; *T. apiforme* (a European species), breeds in the roots and lower parts of the trunks of poplar and willow; *Bembecia marginata*, roots of the blackberry and raspberry; *Vespa minima sequoia*, breeds in the California redwood (*Sequoia sempervirens*) and pines (*Pinus lambertiana* and *P. ponderosa*) producing thick excrescences on the branches and trunks; *Sciapteron tricincta*, in the canes and trunks of low swamp willows infested with *Cryptorhynchus lapathi* and *Saperda concolor*, also in the poplar; *S. denotata*, habits probably the same as last species; *S. robiniae*, the locust (*Robinia pseudacacia*), also recorded in the poplar; *S. simulans*, in the solid wood of the trunks of red oak; *S. dollii*, in the solid wood of poplar and also possibly the willow; *S. polistiformis*, burrows in the bark and sapwood of both wild and cultivated grapevines; *Tarsa denudata*, in the roots and lower parts of the trunk of alder and ash; *Parharmonia pini*, under the bark of pine; *Podosesia syringæ*, the trunks of lilac, ash, and mountain ash; *P. fraxini*, the trunks of the ash and probably also the lilac; *Sannina exitiosa*, under the bark of the peach and cherry, both wild and cultivated, at the base of the tree and very often beneath the surface of the ground; *S. opalescens*, feeds like the preceding species, in the trunks of the peach and apricot and probably also the cherry; *Sesia rutilans*, in the roots of the strawberry, blackberry, and raspberry; *S. bassiformis*, in the stalks of Eupatorium; *S. rubrofascia*, in the trunks and canes of willow; *S. albicornis*, habits like the last; *S. culiciformis americana*, in Nevada in the trunks and stems of alder; *S. aceris*, bores under the bark of the maple, especially *Acer dasycarpum*; *S. corni*, under the bark of maple; *S. tipuliformis*, in the stems of the cultivated currant, in Europe in the young shoots of hazel; *S. pyri*, in the trunks of pear and apple, between the outer bark and sapwood; *S. scitula*, under the bark of chestnut, oak, and dogwood, likewise in the oak galls (*Audricus cornigerus*), and in galls on willow and hickory; *S. rubristigma*, bred from the oak gall (*Audricus cornigerus*); *S. sigmoidea*, taken from willow; *S. quercis*, bred from galls found on live oak in Arizona; *S. prosopis*, raised from galls found on mesquite in Arizona; *S. pictipes*, under the bark of plum, cherry, peach, plum, chestnut, and juneberry (*Amelanchier canadensis*); usually bores under the bark some distance up from the base; it also feeds in the black knot fungus;

*Pyrrhotenia floridensis*, moths have been taken on scrub oak, and it is thought that the larvæ may feed on this tree.

**Two insect pests of 1896**, J. H. PANTON (*Rpt. Ontario Ent. Soc.*, 1896, pp. 44-54, figs. 12).—The two insects noted are the army worm (*Leucania unipuncta*) and the tussock moth (*Orgyia leucostigma*). A map shows the distribution of the first; 39 counties and 118 townships were affected. Of the crops attacked 58 per cent were oats, 20 per cent corn, 16 per cent wheat, and 5 per cent barley. In some cases the loss in oat fields was reported to be 50 per cent, but in most cases the damage was comparatively slight. In a few cases the whole crop was destroyed.

Observations made on the rate of travel while crossing a lane between two fields showed that they moved at the rate of 40 rods per hour.

The following summarizes experiments with several food plants: Clover, eaten very sparingly, quickly left for wheat or oats; lucern, less attractive, not touched for four days; with clover, beans, and lucern in the same box, hunger drove the worms to eat beans first, clover second, and alfalfa last. Peas were not touched for two days, or not as long as oats were accessible. Turnips, left untouched for a day, deserted as soon as a leaf of corn was put in the box. Potatoes, left untouched. Mangel-wurzels near one of the infested fields escaped damage, though the worms were constantly passing over and among them. In the box they were slightly nibbled. Beets, untouched for three days. Buckwheat tried after the first day, immediately left for corn when this was presented to the worms. Carrots, not eaten for a day, but at the end of the second day were fairly well eaten; not touched in presence of grass or corn. Cucumber vines, preferred to beans, eaten almost as greedily as some corn leaves. Celery, always avoided, the worms devouring one another before they would feed upon it. Maple leaves were avoided. Apple leaves, sparingly eaten after two days. Grape leaves, eaten when driven by hunger. Strawberry leaves, not touched until the third day. Currant leaves, eaten sparingly after three days. Canadian thistles remained untouched. If no food was put in the box containing caterpillars, they began devouring one another within twenty-four hours. It appears from these experiments that the insect decidedly prefers the Gramineæ, and that it will not feed upon leguminous plants and some other orders unless compelled by hunger.

Among the natural enemies are mentioned *Calosoma calidum*, *Harpalus caliginosus*, *Tachina flavicauda*, *Ichnemon leucanie*, and *Ophion purgatus*. The usual remedies, such as furrowing, spraying with Paris green (1 lb. to 75 gal. water), rolling, spraying with kerosene emulsion, and burning windrows of straw after the insects have concealed themselves therein are noted.

**Report of the entomological section**, C. P. GILLETTE (*Colorado Sta. Rpt.* 1897, pp. 55-61).—The author notes some experimental work

undertaken for the purpose of throwing light on the life history of the cutworm and other night-flying moths. It is found as a rule that male and female moths are attracted to light or sugar in about equal numbers, and that males fly for a few days or even for as much as a week before the female of the same species. The females are much more readily captured before the deposition of eggs than after.

Data were also collected on the relative value of different remedies against the codling moth, and it was concluded that bandages employed for the destruction of the larvæ may be of great service, while but slight protection is obtained by destroying the fallen infected fruit.

The author also gives notes on the following insects: Peach twig borer and fruit worm (*Anarsia lineatella*); strawberry leaf roller (*Phloxopteris comptana*); oak carpenter worm (*Prionoristus robiniaæ*); green lice (*Hyalopterus pruni*), which seem to attack American varieties of fruit more than European and did a very considerable amount of damage during the year; black lice on plum and cherry; the apple aphid (*Aphis mali*); the elm aphid (*Schizoneura americana*), for which kerosene emulsion in ordinary strength and whale-oil soap in the proportion of 1 lb. to 8 gal. were found to be very effectual remedies; cottony maple scale (*Pulvinaria innumerabilis*), which affected very seriously the soft maples in Denver; harlequin cabbage bug (*Murgantia histrionica*), which was reported to the experiment station for the first time, specimens being sent from Kit Carson County, where the insect was said to be doing great harm; and the Mediterranean flour moth (*Ephestia kuehniella*).

An investigation of a case of what appeared to be bee paralysis is also briefly mentioned and attributed to the bees having eaten some fungus parasite of plants.

From the observations made by several persons it is thought that the first brood of the peach twig borer bores in the spring into tender shoots of peach, plum, apricot, and almond, and that the second brood bores into the fruit of the peach, while the third or fall brood bores into the crowns of strawberry plants. The oak carpenter worm has done considerable damage, but the only remedy thought worthy of suggestion is the plugging of the burrows of the insect with wooden plugs as soon as their castings indicate the presence of the worms.

**Report of the entomologist, H. A. MORGAN** (*Louisiana Stas. Bul.* 48, 2. ser., pp. 128-159, pls. 5, figs. 18).—The author reviews the legislation of the State relative to insects, and gives accounts of the following insects: The cotton mite, a new peach insect (*Artace punctistriga*), the fig borer (*Pitychodes trivittatus*), the harlequin bug (*Murgantia histrionica*), the peach and plum leaf sawfly (*Caliroa* [*Selandria*] *obsoletum*), pecan caterpillar (*Datana integerrima*), leaf footed bug (*Leptoglossus phyllopus*), a new insect attacking corn (*Delphax maidis*). An account is given of finding maggots in the human alimentary canal. The insect proved to be *Hermetia illicens*, which infests lettuce, and it

is to the affected person's eating this that the peculiar occurrence is attributed. The maggot and adult are figured. In most cases a description is given of the insects, enemies mentioned, and their habits, and the proper remedies are noted.

The new peach insect was found late in October, 1894, upon peach trees, in the vicinity of Baton Rouge.

A brief account of insecticides and their preparation is given. At the end of the bulletin there is a list of parasites bred from the eggs, larva, and pupa of various insects.

**The San José scale in Ohio**, F. M. WEBSTER (*Ohio Sta. Bul. 81*, pp. 177-212, figs. 13).—The author discusses recent work with regard to the insect; relates how it came to be introduced into Ohio; discusses the nursery problem; gives a report of the National Convention held at Washington, D. C., March 5, 1897, for the purpose of considering the subject of quarantining the fungus and insect enemies of plants; discusses the distribution of the scale by infested fruit and otherwise, and the treatment of nursery stock, orchards, and grounds; and notes the natural enemies of the scale, the necessity for drastic measures of repression, the difficulty of detecting the scale, and the trees attacked.

Twenty-three different places in the State, located in twenty counties, are now known to be infested with the scale.

For preventing the spread of the insect through nursery stock, a system of annual inspection by entomologists, and legislation to prevent the transportation from one State to another of all nursery stock unless it be accompanied by an official certificate, are advocated. The problem of preventing the distribution by means of fruit, it is stated, may be solved in the orchards where the fruit is grown.

The treatment of nurseries and nursery stock may be by the hydrocyanic gas method, which may be used in the case of large trees should it seem profitable to do so. In the case of large trees the author seems to think it doubtful whether the scale can be exterminated where it has become permanently established without sacrificing the tree.

As to remedies the author thinks, all things considered, the best results have been obtained with whale-oil soap, used at the rate of 2 lbs. to a gallon of water. But good results have been obtained by cutting back trees and treating them with pure kerosene oil applied with a brush or as a spray. The kerosene should be of a high grade and should be applied in fair weather when it can evaporate quickly. Several experiments with the remedy are reported. In some cases injury was done and in one case the tree was probably killed.

In the author's opinion, as ordinarily applied the remedy can not be safely used on peach trees or on tender varieties of plums, but if applied lightly it can be used with entire safety on plums, pears, and apples, especially when the trees are cut back. The most satisfactory effect will be obtained if applied early in the fall or late in the spring, or at both times.

No hope whatever is held out for material aid from natural enemies, though the black lady beetle (*Pentilia misella*) and the twice-stabbed lady beetle (*Chilocorus bivulnerus*) are mentioned.

In discussing the subject of distribution it is shown that the pest may be carried to a considerable distance by birds, or the young scale may be carried on the bodies of ants, grasshoppers, or, in fact, any insect frequenting the branches of trees where the scales occur. The wind is also an important factor, for it has been noted that the scales have been scattered for a much greater distance from the trees on which they were introduced in the direction of the prevailing winds of the season.

It is stated that the insect most likely to be confused with the scale is the Putnam scale (*Aspidiotus ancylus*). According to the author's observations, the quince does not suffer as badly as other fruit, while the Early Richmond cherry seems proof against the scale and the mulberry is not attacked at all.

**Notes on the treatment of the San José scale, with directions for winter work,** W. B. ALWOOD (*Virginia Sta. Bul. 72, pp. 11*).—This bulletin is mostly made up from notes from a series of experiments on the use of washes, etc. The resin and the salt-sulphur-lime washes so successful on the Pacific coast were found to be of little value; nor were any of the lye, soap, or kerosene emulsion preparations entirely satisfactory. Kerosene of the 120° flash test, although it killed all the insects, was not satisfactory, inasmuch as it affected the trees. Where potash solutions were fairly successful they were used in very strong solutions. The soap solutions, even when very strong, it was found must be applied with a brush. In only one instance was eradication of the insect successful.

With regard to winter treatment, it is shown that it is necessary to remove the rough outer bark in the treatment of young orchards before spraying with the soap preparations. It is believed that pure kerosene may be used with safety on all hardy fruit trees in such orchards, but it is not well at present to recommend its use by untrained persons. In the treatment of old orchards the trunk and branches should be cleared, and in all cases except peach, cherry, and pear trees kerosene may be used if care be taken only to moisten the bark with it. A further caution is to use it on a bright warm day, when the plants are dry and when evaporation will take place quickly. For peach and cherry trees a soap wash is thought safest.

In the case of small fruits, shubbery, etc., where possible the entire top should be cut away and destroyed. If a wash be used it should be one made from a potash soap. If kerosene be used it should not be lower than 120° flash test, since low grades are more injurious than high ones. Inasmuch as 40 gal. of the oil will spray from 300 to 400 trees, according to size, this remedy is not thought expensive.

The scale has been found in Virginia upon the following plants: Apple, pear, peach, plum, cherry, apricot, quince, raspberry, currant, gooseberry, grape, strawberry, rose, linden, elm, Osage orange, golden willow, silver maple, mountain ash, and actinidia.

**A fungus disease of the San José scale, P. II. ROLFS** (*Florida Sta. Bul. 41, pp. 518-543, pls. 2*).—The value of fungus diseases in controlling insects is discussed, and the discovery, in May, 1896, of a fungus (*Spharostilbe coccophila*) attacking the San José scale with deadly effect is reported. The decrease of the fluted scale in Florida (E. S. R., 9, p. 575) is attributed to the action of this fungus. Its attacks on various scale insects have been noted by a number of observers. T. D. A. Cockerell reports it from Jamaica as attacking *Aspidiotus articulatus*. It is a common disease of *Aspidiotus obscurus*, on which it was discovered by A. L. Quaintance in 1896. Since then it has been found in Florida at De Funiak, on the oak.

The disease was experimentally disseminated by twigs infested by diseased bugs. The spores were grown on bread; acid, neutral, and alkaline agar; gelatin, and sterilized potatoes. Trees were sprayed with water in which infected bread had been soaked. On trees thus sprayed the disease took hold and spread rapidly. Wrapping the sprayed parts of the trees with cloths was found to accelerate the process greatly.

The author describes the growth of the fungus, and states, among other things, that when grown in strong liquid medium the mycelium seems to have the power of inhibiting the growth of spores. In cell cultures a great many spores collect near the mycelium, but do not germinate. When removed by only the fraction of an inch, a great many of them germinate. When removed to the outer edge of the hanging drop, the normal proportions germinate.

The fungus appears to have great powers of adaptability as to medium, temperature, and moisture. Acid media, however, seem better suited to it than alkaline, and slightly acid bread best of all.

In conclusion, it is noted that the best time to apply the material is after sundown in moist weather. The spores grown on bread germinate in a few hours and must find a suitable medium or they will perish, while those produced in the orange-colored protuberance formed on the scale will live for several months in dry weather. The material can be produced in great quantities, and its application to insects by a spray is an easy matter. Another point in its favor is that it is more thorough than insecticides. It is probably best adapted to moist climates. As soon as the insects have been killed they and the fungus are washed from the tree by rains, leaving no signs behind them save where the scales have injured the tree.

**Notes on some European hymenopterous parasites of the Hessian fly (*Cecidomyia destructor*) and other insects, W. H. ASHMEAD** (*Psyche, 1897, No. 259, pp. 135-138*).—A description is given of new species of parasites received in a lot of parasites bred from

*Cecidomyia destructor* and *C. avenæ* by Dr. Paul Marchal, Government Entomologist of France. From *C. destructor* Marchal bred the following: *Bæotomus* (*Micromelanus*) *rufomaculatus*, ♀; *B. coxalis*, n. sp., ♂ ♀; *Merisus destructor*, ♂ ♀; *Holcivus cecidomyiæ*, n. sp.: *Eupelmus atropurpureus* ♀ ♂; *Polygnotus* (*Platygaster*) *zosiæ*, ♂. A single male specimen of *Isosoma brevicorne* was found in the lot and Marchal reports *Oscinis pusillus* as occurring in oat stubble. The specimens of *Bæotomus coxalis* were found at Poitou and in various parts of Vendée in France. It was also bred by Marchal from *Cecidomyia* (*Oligastrophus*) *avenæ* infesting oats. According to Ashmead the species comes near *B.* (*Merisus*) *subapterus* of Riley, but it is readily distinguished from that form by the metallic coxæ, darker flagellum, the longer funicular joints, and by its broader and more depressed abdomen. From *Merisus microptera* Lind. it seems fairly distinct.

In the winged form the female has a length of 2 mm., is of a general bronzed green color, with purplish head and lower part of thorax. The palpi are white; the scape of the antennæ, except apically, and the legs, except the coxæ, are brownish yellow; while the knees, the tips of the tibia and the tarsi, except the last joint, are yellowish white. The flagellum is brown, subclavate, and pubescent. The male, or subapterous form, is usually 6 mm. in length. It is of the same general color as the female; the scape and pedicel are brownish yellow; the flagellum is filiform, dark brown, and clothed with a fine pubescence. The mandibles are quadridentate and ferruginous. The coxæ are metallic and the abdomen black, becoming brassy towards the base.

*Holcivus cecidomyiæ* is a somewhat larger insect; the thorax is olive green, the scape, trochanters, knees, tibia, and the tarsi, except the last joint, honey yellow. It was bred in June from the Hessian fly attacking wheat. According to Ashmead, it is closely related to *H. torymoides* of Thomson, but is readily distinguished from that form by the color of the female, the shorter abdomen, the relative length of the segments, and the flagellar joints. The male is very readily distinguished by the very long joints of the flagellum clothed with black instead of white pili.

From *Cecidomyia avenæ* Marchal bred *Bæotomus coxalis*, *Merisus destructor*, *Homoporus luniger*, *Eupelmus atropurpureus* (= *atroceruleus* of Thomson), *E. degeeri*, *Trichacis* (*Platygaster*) *remulus*, *Polygnotus* (*Platygaster*) *minutus*, and *Anaphes pratensis* (an egg parasite). With them were found specimens of *Isosoma brevicorne* which is thought by Ashmead to be a gall maker on oats, since most of the specimens were bred from insects taken from oat stubble.

From *Cecidomyia tritici* a single species, *Merisus destructor*, was bred.

**Preliminary studies of North American Gomphinae**, J. G. NEEDHAM (*Canad. Ent.*, 19 (1897), No. 8, pp. 181-186, pl. 1).—The name *Oreus* is replaced by *Arigomphus*. Several new species are described.

**The Acridian subfamily Mastacinae in the United States**, S. H. SCUDDER (*Psyche*, 1898, No. 262, p. 179).—Specimens representing a new generic type closely

allied to Masynates of Karsch, but differing from it in having a more appressed head and less convex vertex and broadly convex and prominent fastigium, were found near Los Angeles, California. The name *Morsca californica* is given them. The body is cinereous with a broad black median stripe on the vertex and the upper half of the lateral lobes of the pronotum and on the abdomen. The length is only 9 mm.

**Notes on some species of North American moths, W. BEUTENMÜLLER** (*Bul. Amer. Mus. Nat. Hist.*, 9 (1897), pp. 209-212, fig. 1).—The two new varieties, *Catocala faustina carlota* and *C. stretchii sierræ*, are described. The first is figured.

**Notes on North American Sesiidæ, with descriptions of new species, W. BEUTENMÜLLER** (*Bul. Amer. Mus. Nat. Hist.*, 9 (1897), pp. 213-216).—The new variety, *Sciapteron dollii carlota*, and the new species, *Sesia sigmoidica*, *S. ithacæ*, and *Zenodorus mexicanus*, are described. The first new species was found at Walpole, Massachusetts, the second at Ithaca, New York.

**Diptera of the Mesilla valley of the Rio Grande in New Mexico, I. C. H. T. TOWNSEND** (*Psyche*, 1897, No. 260, pp. 147-150).—Tabanidæ, Syrphidæ, Conopidæ, Gymnosomatidæ, Ocypteridæ, and Tachinidæ *sensu stricto*.

**The Coleoptera of Canada, XXVI. The Cerambycidæ of Ontario and Quebec, H. F. WICKHAM** (*Canad. Ent.*, 29 (1897), No. 8, pp. 187-193, figs. 2).

**Contributions to experimental lepidopterology, II, E. FISCHER** (*Illus. Wehnschr. Ent.*, 2 (1897), No. 37, pp. 577-583, figs. 8).—Experiments with *Vanessa urticae* and *V. aberratio ichneusoides* with low temperatures, demonstrating that cold may cause development to take a different direction from the normal.

**Contributions to experimental lepidopterology, III, E. FISCHER** (*Illus. Wehnschr. Ent.*, 2 (1897), No. 38, pp. 595-600, figs. 6).—Experiments with *Vanessa polychlora* and *V. aberratio testudo*.

**A new Lecanium on magnolia from Florida, T. D. A. COCKERELL** (*Psyche*, 1897, No. 260, p. 152).—*Lecanium turgidum*, common on *Magnolia glauca* and *M. grandiflora* at Lake City, Florida. The young appear in rather large numbers in April, and apparently during the year finish their life cycle.

**A new ant nest coccid, G. B. KING and T. D. TINSLEY** (*Psyche*, 1897, No. 260, pp. 150, 151, figs. 2).—*Dactylopius clariger*, n. sp., is noted.

**On a new species of Forficularia, M. BURR** (*Ann. Mag. Nat. Hist.*, 6. ser., 20 (1897), No. 117, pp. 310-316).

**Some further remarks on Otiorhynchus ligustici, M. HOLLRUNG** (*Illus. Wehnschr. Ent.*, 2 (1897), No. 35, pp. 549, 550).—The insect is said to be subject to the attacks of a species of Botrytis. Various remedial measures suggested are Antinonnia, Schweinfürter green, dilute carbon bisulphid, and alcoholic soap solution. The first generation of the insect appears as early as the end of February. Pupæ have been found in the middle of July. Larval development is slow.

**Synonymical and critical observations on Tenthridinid species hitherto not or incorrectly so called, W. KONOW** (*Illus. Wehnschr. Ent.*, 2 (1897), Nos. 16, pp. 250-254; 17, pp. 267-269; 18, pp. 281-284; 19, pp. 296-298; 20, pp. 314-320).

**Notes on the Lerp insect (Psyllidæ) of Australia, E. A. SCHWARZ** (*Proc. Ent. Soc. Washington*, 4, No. 2, pp. 66-75).—A new genus and species, *Cardiaspis artifex*, is described.

**The compound eye of the Ephemeroïdæ, C. ZIMMER** (*Ztschr. Wiss. Zool.*, 63 (1897,) pp. 236-262, pls. 2; *abs. in Zool. Centbl.*, 5 (1898), No. 3, pp. 87-89).

**The intestinal canal of the larva of Arthrenus, with remarks on the regeneration of its epithelium, A. MÖBUSZ** (*Arch. Naturgesch.*, 63 (1897), No. 2, pp. 89-128, pls. 3; *abs. in Zool. Centbl.*, 5 (1897), No. 3, pp. 89-91).

**On a peculiar organ of the bedbug, C. RIBAGA** (*Riv. Path. Veg.*, 5, No. 9-12, pp. 343-353, figs. 4, pl. 1).—A microscopic study of what is believed to be a stridulating organ situated in the hinder margin of the right side of the ventral part of the fourth abdominal ring of the bedbug (*Cimex lectularius*) is reported.

**On the white Eucleidæ and the larva of *Calybia slossoniæ***, H. G. DYAR (*Jour. New York Ent. Soc.*, 5 (1897), No. 3, pp. 121-126, pl. 1).—The 5 species of *Calybia* noted are distinguished as follows: *C. immaculata* by the inside of the primaries being entirely white; in all the others this side is partly gray, especially along the costa. *C. slossoniæ* is to be distinguished by the primaries being white above and by a yellowish spot near the angle in the male. *C. pigma* has white primaries and shows a distinct zigzag yellowish brown mark above the anal angle. *C. fumosa* instead of entirely white has a subterminal smoky band on the primaries, and in *C. jamaicensis* the secondaries are gray above instead of white, as in the last 3 forms. The two species, *Leucophobeton argentiflua* and *L. agyrorrhæa*, are distinguished by a large dark spot above the anal angle of the wings of the former species and by the wings being immaculate white in the latter.

**On the habits of *Coccinella 7-punctata***, K. SAJO (*Illus. Wchnschr. Ent.*, 2 (1897), No. 34, pp. 529, 530).—Cannibalistic habits are noted, also that the larva feeds on *Cochylis ambiguella* and in all probability on *Lema melanopsus*.

**The cases of the German Phryganids**, RUDOW (*Illus. Wchnschr. Ent.*, 2 (1897), No. 29, pp. 451-456, figs. 26).

**The enemies of the butterflies**, A. PREHN (*Illus. Wchnschr. Ent.*, 2 (1897), No. 30, pp. 465-469).

**On the post alar membrane of Diptera**, E. GIRSCHNER (*Illus. Wchnschr. Ent.*, 2 (1897), Nos. 34, pp. 534-539, figs. 8; 35, pp. 553-559, figs. 5; 36, pp. 567-571, figs. 7; 37, pp. 586-589; 38, pp. 603-607, figs. 2; 41, pp. 641-645, figs. 23).

**Nocturnal larva hunting**, SCHENKING-PRÉVÔT (*Illus. Wchnschr. Ent.*, 2 (1897), Nos. 31, pp. 487-492; 32, pp. 502-505).—Mostly short descriptions of larvæ to be found during the several spring and summer months.

**A curious case of protective coloration**, T. D. A. COCKERELL (*Psyche* (1897), No. 260, p. 154).—The pupæ of *Pyrameis cardui* are so colored as to be hidden in blossoms of *Baileya multiradiata*. The larvæ feed only on *Solanum elæagnifolium* and seem to warder to the blossoms of the other plant to pupate.

**A principle to observe in naming galls**. Two new gall-making diptera, W. H. PATTON (*Canad. Ent.*, 29 (1897), No. 10, pp. 247, 248).—The principle consists in writing the name of the genus of the host plant with the name of the genus of the gall makers, connecting the two with a hyphen. Applying the principle the author changes the names of the galls described in the Fifth Report of the United States Entomological Commission to *Cecidomyia-celtis oriformis*, *C. semcroumiciis*, *C. pubescens*, *C. capsularis*, and *C. spiniformis*. The new species are *Edaspis-solidago atra*, the galls of which do not differ from those of *E. polita*, and *Cecidomyia-celtis* (new genus) *deserta*. The galls of the latter are hollow elongate swellings of young twigs from which the flies emerge about the first of June.

**Gall wasps of oaks**, C. KELLER (*Jour. Suisse Econ. Forest.*, 1896, No. 2).

**Chinese insect white wax**, G. F. SMITHERS (*U. S. Consular Rpts.*, 1897, No. 203, pp. 484-490).—The best of the insects (*Coccus pe-la*) that produce white wax are found in the Chien-Ch'ang Valley. Those from elsewhere bring a lower price, where they are found on the evergreen, *Ligustrum lucidum*, which has various local names, as ch'ung shu, or insect tree; tung ching shu, or evergreen tree; and pao-kê-ts'ao shu, or crackling flea tree. The insects from Chien-Ch'ang Valley, found for the most part near the town of Tê Chang on the Au-ning River (latitude 27° 24'), are transported to the plain north of the Ta-tu River north of Chien Ch'ang, where they are placed on the wax tree, *Fraxinus chinensis*, known to the Chinese as the pai la shu. One pound of the scales produces 4 to 5 lbs. of wax. The process of obtaining the wax is described.

**Renewing of queens**, DEVAUCHELLE (*L'Apiculteur*, 42 (1898), No. 1, pp. 14-17).—The author's practice is to destroy few queens, and only those manifestly poor layers or otherwise bad. It is not necessary to renew them every three years.

**Humidity of hives during winter** (*L'Apiculteur*, 41 (1897), No. 11, pp. 444-454).—A critical summary of the ideas of various authors on the subject.

**A garden pest, *Creoceris lilii* Scop. (merdigera F.)**, C. SCHRÖDER (*Illus. Wechschr. Ent.*, 2 (1897), No. 33, pp. 516-518, figs. 4).—The eggs are laid about the first of May and hatch about fourteen days later. The larvæ attack the leaves of *Fritillaria imperialis*, eating the upper surface and the parenchymatous tissue below it to the epidermis of the under side. The latter and the veins are left untouched. Finally they eat away the leaf at its edge. Since full-grown insects and larvæ are found at the same time on the food plant it is probable that there are several broods a year. According to Bos the winter is passed in the pupal state, but the author is inclined to think that the fertilized female lives through the winter. When the beetles occur in large numbers they do a very considerable amount of damage.

**Notes on scale insects, II**, T. D. A. COCKERELL (*California Fruit Grower*, 20 (1897), No. 23, pp. 4, 5).—The following new species appear, along with brief descriptive notes: *Aspidiotus andromalas*, *A. crawii*, *A. greenii*, *Chionaspis latissimus*, *Dactylopius edgeworthii*, *Mytilaspis pallida maskelli*, and *Parlatoria theae eunymi*.

**Otiiorhynchus ligustici**, H. GAUCKLER (*Illus. Wechschr. Ent.*, 2 (1897), No. 33, pp. 524, 525).—The proper food plant of this wingless beetle appears to be alfalfa, though its larva does not dislike the peach and the grape. It often attacks the roots of the latter and does great damage. The beetles eat mostly at night and consequently are found in small numbers during the day.

**Our *Blissus doriæ***, K. SAJO (*Illus. Wechschr. Ent.*, 2 (1897), No. 29, pp. 449-451).—This species is compared with its American relative, *B. leucopterus*. It does not go into cultivated fields and is not so easily affected by *Sporotrichum globuliferum*.

**A concealed enemy of the raspberry**, G. MÜLLER (*Illus. Wechschr. Ent.*, 2 (1897), No. 30, pp. 469-471, figs. 8).—A portion of the life history and the habits of *Bembecia hyalaformis* are described. The insect sometimes attacks the cultivated raspberry. The larva is found in the interior of the young shoots, seldom in those of the previous year's growth—almost always with the head directed upward. The author states that the moth is not exclusively nocturnal, and that there are two broods a year. A number of braconid and ichneumon parasites of the insect are known. *Meniscus pimplator* and *Bracon regularis* are mentioned.

**Insect enemies of potatoes**, I. P. ROBERTS and L. A. CLINTON (*New York Cornell Sta. Bul.* 140, pp. 391, 392).—Brief notes are given on the leaf flea beetle and Colorado potato beetle, with suggestions for their destruction.

**The use of arsenites on tobacco**, H. GARMAN (*Kentucky Sta. Rpt.* 1896, pp. 69-80, pls. 2).—A reprint from Bulletin 63 of the station (E. S. R., 8, p. 319).

**Triconympha and other parasites of *Termes flavipes***, J. P. PORTER (*Bul. Mus. Comp. Zool.*, 31 (1897), No. 3, pp. 47-67, pls. 6).—This deals with *Trichonympha agilis*, *Pyrsonympha verteus*, *Dinenympha gracilis*, and Gregarinida—protozoan parasites.

**The large libellulids considered as useful animals destroying noxious insects**, R. MARTIN (*Excerpt from Bul. Soc. Nat. Acclim. France*, 1897, pp. 4).

**Report of the entomologist**, H. GARMAN (*Kentucky Sta. Rpt.* 1896, pp. XXIV-XXVIII, figs. 3).—The author notes that complaint of insect depredations in Kentucky were more than usually frequent during 1896. Requests were received for the parasite fungus for the destruction of chinch bugs from thirteen different counties. The objection to the use of the fungus that the bugs are slowly affected by it is noted, but it is thought this defect may be overcome to a certain extent by sending larger packages. The army worm is mentioned as doing considerable injury.

**Analyses of Paris green**, W. C. STUBBS (*Louisiana Stas. Bul.* 49, 2. ser., pp. 198-204).—The text of the State law relating to Paris green is given, the use of Paris green in Louisiana is discussed, and analyses of thirty-nine samples are reported. The samples of Paris green sold on our market show, as a rule, high percentages of arsenious acid (white arsenic), all but one being well above the requirements.

## FOODS—ANIMAL PRODUCTION.

**A digest of metabolism experiments in which the balance of income and outgo was determined,** W. O. ATWATER and C. F. LANGWORTHY (*U. S. Dept. Agr., Office of Experiment Stations Bul. 15, pp. 433*).—In view of the fact that some of the experiment stations are carrying on metabolism experiments, the attempt was made to gather as many as possible of such experiments made in the United States and other countries up to 1895 with man and animals in which the balance of income and outgo of matter and energy was determined. The balance of matter is usually expressed in terms of nitrogen, with or without mineral matter; or nitrogen and carbon, with or without mineral matter, oxygen or hydrogen. The balance of energy is expressed in terms of heat. Over 3,600 individual tests or averages are included in the compilation. Of these about 2,300 were made with man, about 400 with cattle and horses, 950 with sheep, dogs, and other domestic quadrupeds, and 51 with poultry and doves. In about 3,400 experiments the balance of nitrogen and in about 300 the balance of carbon was determined.

The experiments with men, women, and children included in the compilation were made under various conditions of health and disease. Those with animals were usually made under normal conditions for the study of various economic problems, although some were made under other conditions for special purposes. In compiling the results the date and original source of publication of the investigation, the observer, the subject with age and weight, food consumed, duration of experiment, and the nitrogen (or nitrogen and carbon with or without other elements) in the food and excretory products are included in tables. In text accompanying the tables the experiments are described, the methods followed are given, and the deductions drawn from the experiments are cited.

The experiments with man in which the nitrogen balance was determined are arranged in three general groups—(1) healthy subjects, influence of diet; (2) healthy subjects, influence of other conditions than diet; and (3) diseased subjects. The first group includes experiments with a vegetarian diet, milk diet, bread and other single-food materials, alcoholic beverages, kephir, koumiss, peptones, and similar preparations, to determine the amount of protein required, and miscellaneous. The second group includes experiments with fasting subjects, drugs, and on the influence of muscular exertion, massage and faradization, baths and enemas, pregnancy, childbirth, menstruation, copious and diminished water drinking, and compressed air. The third group includes specific infectious and constitutional diseases and diseases of the digestive system, respiratory system, circulatory system, blood and ductless glands, kidneys, nervous system, and bones. The experiments with man in which the income and outgo of carbon was determined,

*i. e.*, respiration experiments, form a group by themselves and are not subdivided. The experiments in which the nitrogen balance was determined with cattle, dogs, doves and poultry, goats, horses, rabbits, sheep, and swine constitute separate groups. The experiments with animals in which the income and outgo of carbon was determined form a group by themselves, as do also the experiments with animals in which the income and outgo of energy was determined.

The purpose of the compilation is primarily to give a brief epitome, so far as practicable, of the objects and results of individual tests. The tables furnish the framework of such epitome, while supplementary matter is given in the accompanying text.

The bulletin includes an introductory chapter giving historical information concerning the subject, explaining the scope and plan of the compilation, and calling attention to some of the points to be considered in drawing deductions from the experiments. A name and subject index is appended.

**Dietary studies in New York City**, W. O. ATWATER and C. D. WOODS (*U. S. Dept. Agr., Office of Experiment Stations, Bul. 46, pp. 117*).—Twenty-two dietary studies of families living in a congested portion of New York City are reported, together with studies at a mission and a day nursery in the same region. The methods followed in making the investigation were practically the same as those described in Bulletin 21 of this Office. The families were selected as typical of the so-called poor classes usually encountered by philanthropists and mission workers in the congested districts of large cities.

Tables are given showing the kind and amount of food purchased, wasted, and eaten, and its cost, composition, and fuel value. The more technical details of the studies are included in an appendix. The results of the studies are briefly summarized as follows:

*Results of dietary studies—cost and composition of food eaten per man per day.*

	Cost.	Protein.	Fat.	Carbo- hydrates.	Fuel value.
	<i>Cents.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Calories.</i>
Mechanic's family.....	31	149	128	526	3,955

Children at a day nursery (per child per day).....	4	30	20	120	800

From the data available the authors do not feel warranted in drawing specific deductions. Some general suggestions for the improvement of the dietaries are, however, made. By the selection of cheaper, though equally nutritious, articles of food it would as a rule have been possible to supply a more nutritious diet at less cost. In many instances, while the foods chosen were inexpensive, they were of such a character that they contained a small percentage of nutrients. Purchasing in quantity, where possible, would also have diminished the cost. Some of the families studied had a sufficient income to enable them to live comfortably if care had been exercised in its expenditure. The authors believe that permanent improvement must come through education. The people must be taught to select food wisely and to cook it and serve it in an acceptable manner.

**Report on the dietaries in nine institutions of the city of Boston,** ELLEN H. RICHARDS and SARAH E. WENTWORTH (*Institutions Commr., Boston, Rpt. 1896, pp. 206-219*).—On the basis of raw materials furnished and number of persons fed the dietaries of the inmates of a number of houses of correction and other institutions in the city of Boston were calculated. The results are briefly summarized in the following table:

*Calculated amount and cost of nutrients consumed per person daily.*

	Number of persons fed.	Cost.	Protein.	Fat.	Carbohydrates.	Fuel value.
		<i>Cents.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Grams.</i>	<i>Calories.</i>
South Boston House of Correction.....	523	9. 89	153	78	501	3, 406
Deer Island House of Correction.....	1, 754	7. 34	122	69	624	3, 700
Rainford Island House of Reformation.....	125	8. 07	103	60	414	2, 677
Parental School.....	125	5. 29	70	40	346	2, 078
Marcella Street Home.....	333	8. 37	95	55	380	2, 459
Long Island Almshouse and Hospital.....	833	7. 73	109	48	554	3, 164
Charlestown Almshouse and Hospital.....	145	7. 54	71	72	355	2, 415
Austin Farm (inmates and employees).....	375	12. 94	110	114	449	3, 327
Pierce Farm (inmates and employees).....	194	18. 85	138	180	471	4, 171

The amounts of food eaten by the officers in a number of these institutions are also recorded, though the composition of the diet is not calculated. The dietaries are discussed at some length and compared with the commonly accepted dietary standards. Improvements are suggested.

**Experiments in fattening sheep,** J. GRUDE (*Aarsber. Offent. Foranst. Landbr. Fremme, 1896, pp. 277-289*).—In continuation of work previously reported (E. S. R., 5, p. 919; 8, p. 154), the agricultural society of Stavanger County, Norway, conducted experiments with sheep. Two hundred and sixty sheep were used in all, divided into lots of 10 each. The actual feeding was carried on according to directions furnished by the society on 13 different farms, with 2 lots at each place. Of the total number of animals 50 were wethers 1½ years old, 80 wethers 2½ years old, 50 ewes 1½ years old, 40 ewes 2½ years old, and 40 breeding

ewes 4 to 7 years old. The following table shows the average results of the feeding trials:

*Results of sheep-fattening experiments, 1896.*

	Number of animals.	Age of animals.	Average length of fattening period.	Feed per day per 1,000 kg. live weight.				Weight at beginning.	Weight at end.	Increase.
				Hay.	Tur-nips.	Linseed oil cake.	Oats.			
		<i>Years.</i>	<i>Days.</i>	<i>Kg.</i>	<i>Kg.</i>	<i>Kg.</i>	<i>Kg.</i>	<i>Kg.</i>	<i>Kg.</i>	<i>Per cent.</i>
Wethers.....	50	1½	50.2	4.5	75.0	16.6	3.6	44.3	55.5	25.3
Do.....	179	2½	51.8	5.1	69.7	15.1	3.9	51.3	63.4	23.5
Ewes.....	50	1½	51.0	6.5	69.5	16.6	3.9	43.0	53.0	23.4
Do.....	40	2½	51.8	5.5	80.3	15.4	4.4	45.7	56.6	23.9
Breeding ewes.....	40	4-7	65.8	5.1	68.4	15.8	4.1	46.3	57.5	24.4
Totals and averages...	259	.....	53.3	5.3	71.7	15.7	4.0	46.9	57.9	24.0

<sup>1</sup>One animal died in the early part of the experiment.

The following conclusions were reached: The fattening period should not extend beyond 40 days. Full value may be obtained for home farm products by fattening sheep under conditions similar to those here reported.—F. W. WOLL.

**Feeding experiments with chicks and capons, W. P. WHEELER** (*New York State Sta. Bul. 126, pp. 307-325, pl. 1, figs. 2*).—Tests were made with chickens and capons to compare the value of whole and ground grains as commonly fed. The principal test was begun with 2 lots of 22 chickens each. Lot 1 was fed finely ground grain, the basis of the ration being a mixture of corn meal, wheat bran, wheat middlings, old-process linseed meal, and oats, 2:2:1:1:1. This was supplemented by skim milk, dried blood, and additional amounts of corn meal and ground oats. Lot 2 was fed either whole or cracked oats, wheat, corn, and barley. In addition some skim milk, fresh-cut bone, and dried blood were fed. The average nutritive ratio for lot 1 was 1:3.3, and for lot 2, 1:4.6.

The composition of the food is reported.

The chickens were hatched in incubators and kept in outdoor lamp brooders surrounded by a small grass run. The test began as soon as the chickens were hatched and covered 92 days. During the whole period both lots made satisfactory growth and remained healthy. Lot 1 consumed 4.56 lbs. and lot 2 4.4 lbs. of dry matter per pound of gain. The cost of food per pound of gain for the 2 lots was 3.33 cts. and 3.76 cts., respectively. If heating the brooders is taken into account also the cost was 3.98 cts. and 4.5 cts. At the end of 12 weeks the average weight of the chickens in lot 1 was 2.9 lbs.; in lot 2, 2.6 lbs., and the average cost per chicken 15.3 cts. and 15 cts., respectively.

The time required to reach 1 lb. weight by lot 1 was 6 weeks, and by lot 2, 7 weeks; the time required to reach 2 lbs. weight was 10 weeks and 10½ weeks, respectively. The cost for the 2 lots of food per chicken to weight of 1 lb. was 3 cts. and 3.7 cts.; to weight of 1.5 lbs., 4.9 cts.

and 5.8 cts.; to weight of 2 lbs., 7.2 cts. and 7.3 cts.; to weight of 2.5 lbs., 8.6 cts. and 9 cts.

At the end of 3 months the 12 roosters in lot 1 and the 7 in lot 2 were caponized and were fed for about 7 months a fattening ration consisting of corn meal, wheat bran, wheat middlings, ground oats, and ground barley, 10:2:1:1:1, with the same supplementary foods as were fed previously. The grains fed to lot 1 were ground and to lot 2 unground. During the first 4 months lot 1 consumed 6.5 lbs. dry matter (costing 7.2 cts.) per pound of gain; and lot 2 consumed 6 lbs. dry matter (costing 6.9 cts.). In 6 months lot 1 consumed 8.6 lbs. dry matter (costing 8.6 cts.) per pound of gain; and lot 2 consumed 7.45 lbs. dry matter (costing 8.3 cts. per pound).

“Considering the total cost of food from hatching, the average bird receiving the ground grain had cost 35.5 cts. at 5 months of age, and weighed 8.1 lbs., thus costing 4.38 cts. per pound. Those fed whole grain weighed 7.5 lbs. and had cost 34 cts., or 4.53 cts. per pound. At 6½ months lot 1 had cost 5.4 cts. a pound for an average weight of 10 lbs., and lot 2, 5.49 cts. per pound for a weight of 9.5 lbs.”

A second trial was begun October 31 with 2 lots of 12 capons under conditions similar to those previously described, and covered about 5 months. Four capons in each lot were dropped several weeks before the close of the test. During the entire period the lot on ground grain consumed 8.3 lbs. dry matter per pound of gain; the lot on whole grain 10.1 lbs. Profitable gains were made only during the first 11 weeks of the test, when the lot on ground grain consumed on an average 6.8 lbs. dry matter (costing 7.2 cts.) per pound of gain, and the lot on whole grain consumed 6.9 lbs. (costing 7.8 cts.). After this time the gains were very slow and about equal for both lots.

From the experiments as a whole the following conclusions were drawn:

“A ration consisting mostly of the ordinary ground grains was more profitably fed to chicks than a ration of whole grain.

“Capon from lot 2 afterwards made a somewhat cheaper gain in weight on the whole grain ration, but the gain was too slow to compensate for the more rapid growth which had been made, as chicks, by lot 1 on ground grain.

“Of two other lots of capons those having the ground-grain ration made the more profitable gain during several months.

“In every trial more food was eaten by the lots on the ground grain than by the lots on whole grain.”

None of the chickens or capons showed any lack of health and vigor.

**Italian paste made from wheat, corn, and a mixture of the two, A. SCALA** (*Bol. Not. Agr., 19 (1897), II, No. 27, pp. 355-364*).—The author reports the composition of macaroni, vermicelli, and other forms of Italian paste made from wheat, corn, and a mixture of the two. The composition of pastes and bread is compared with that of the flour from which they are made.

**The adulteration of Italian paste with corn meal and corn pastes, A. SCALA** (*Bol. Not. Agr., 19 (1897), II, No. 27, pp. 351-354*).—The author points out the difference in percentage composition between Italian paste made from wheat alone and that from wheat with the addition of corn. On the basis of variation in composition a method of detecting adulteration is suggested.

**The adulteration of Italian paste with corn meal and corn pastes, A. SCALA** (*Ann. Ig. Sper., n. ser., 6 (1896), No. 3, pp. 409-423*).—The author discusses Italian paste made from wheat, alone and mixed with corn.

**Maize diet and a way of improving it, A. CELLI** (*Bol. Not. Agr., 19 (1897), II, No. 27, pp. 343-350*).—The importance of maize as a food is insisted upon. Polenta and Italian paste made from corn, corn and wheat, and wheat alone are compared on the basis of their composition, cost, and digestibility.

**Semolina and Italian pastes, BALLAND** (*Compt. Rend. Acad. Sci. Paris, 126 (1898), No. 8, pp. 605, 606*).—Analyses of macaroni and other Italian pastes, semolinas, and tapioca.

**Cocoa as a food, BEDDIES and TISCHER** (*Ueber Kakao-Ernährung. Berlin, 1897; rev. in Hyg. Rundschau., 8 (1898), No. 4, p. 211*).—The authors made a comparative study of a number of cocoa preparations. Digestion experiments are reported of cocoa alone and in combination with other foods.

**Lily bulbs and flowers as food, J. B. DAVY** (*Erythea, 6 (1898), No. 3, p. 26*).—The bulbs of *Lilium japonicum brownii*, *L. cordifolium*, *L. tigrinum*, *L. concolor pulchellum*, and *L. gletkii*, and the dried flowers of *L. bulbiferum* and *Hemerocallis graminea*, are used as food by the Chinese and Japanese.

**The nutritive value of certain patented substitutes for milk, G. B. SOMONCINI** (*Ann. Ig. Sper., n. ser., 7 (1897), No. 1, pp. 99-102*).—The author reports the nitrogen content and digestibility (obtained by digestion with pepsin and hydrochloric acid) of "milk flour" and "chocolate milk."

**Determining the source of different cuts of meat, OSTERTAG** (*Ztschr. Fleisch u. Milchhyg., 8 (1898), No. 6, pp. 101, 102*).

**The use of beef infested with tænia, ZSCHOCKE** (*Deut. Tierärztl. Wchnbl., 1897, No. 52, p. 458*).

**Black pepper from Mangelore, T. F. HANAUSEK** (*Ztschr. Untersuch. Nahr. u. Genussm., 1898, No. 3, pp. 154-156, figs. 4*).

**Adulteration of buckwheat flour sold in the Lawrence market, M. A. BARBER** (*Kansas Univ. Quart., 7 (1898), No. 1, pp. 37, 38, pls. 2*).—A number of samples purchased as pure were examined microscopically. Several were found to be adulterated with wheat starch.

**Seventh report on the health and sanitary condition of the cities of Berlin and Charlottenburg during the years 1892, 1893, and 1894, A. WERNICH and SPRINGFELD** (*Siebenter Gesamtbericht über das Sanitäts und Medicinalwesen in den Städten Berlin und Charlottenburg während der Jahre 1892, 1893, 1894. Berlin: R. Schoetz; rev. in Hyg. Rundschau., 8 (1898), No. 4, pp. 212, 213*).—In addition to other matter, this volume contains a report on the inspection of food.

**Workrooms in bakeries, A. MISCHA** (*Monatsschr. Gesundheitspfl., 15 (1897); abs. in Hyg. Rundschau., 8 (1898), No. 5, pp. 251, 252*).—The need of clean bakeries is insisted upon. Some of the defects of German bakeries are pointed out.

**The dietaries of the students of the University of Padua, A. SERAFINA and F. ZAGATO** (*Bol. Not. Agr., 19 (1897), I, No. 2, pp. 167-201, tables 5*).—See abstract from a German publication of this article (*E. S. R., 9, p. 265*).

**Carob bean as a feeding stuff, F. TUCCI** (*Bol. Not. Agr., 19 (1897), II, No. 19, pp. 86-91*).—New analyses of carob bean or St. John's bread (*Ceratonia siliqua*) and experiments in feeding it to milch cows are reported, and the importance of the carob bean as a feeding stuff is insisted upon.

**Observations and experiments on the nutritive value of carob bean, S. BALDASSARE** (*Bol. Not. Agr., 19 (1897), I, No. 2, pp. 29-48*).—The composition and digestibility of carob bean or St. John's bread is discussed, rations of it are suggested for horses, and feeding experiments with milch cows are reported. In the author's opinion the carob bean is especially valuable food for dairy cows.

**Grapevine foliage as a feeding stuff, F. TUCCI** (*Bol. Not. Agr., 19 (1897), II, No. 18, pp. 64-69*).—The author points out the value of grape leaves as a feeding stuff.

**Possible feeding stuffs for the arid regions of Sicily or for use when fodder is scarce**, F. TUCCI (*Bol. Not. Agr.*, 19 (1897), I, No. 2, pp. 62-85).—The feeding stuffs discussed include the joints of prickly pear, forage beets, prickly comfrey (*Symphytum asperinum*), and the leaves of mulberry, poplar, *Ficus beniamina*, and *Ligustrum lucidum*. Proper feeding stuffs in various combinations for different seasons of the year are suggested.

**The cotton-seed meal on the market**, DIETRICH (*Deut. Landw. Presse*, 25 (1898), No. 13, pp. 133-135).—A general article comparing American and German cotton-seed meal.

**The use of meat meal as a feeding stuff**, S. BALDASSARE (*Bol. Not. Agr.*, 19 (1897), I, No. 2, pp. 49-61).—Experiments are reported on the use of meat meal for calves.

**Physiology of digestion**, H. VIGOROUX (*Jour. Hyg.*, 23 (1898), Nos. 1119, pp. 100-103; 1121, pp. 125, 126).—A brief discussion of digestion, assimilation, balance of income and outgo, etc.

**The influence of the pancreas on the assimilation of food**, S. ROSENBERG (*Arch. Physiol. [Pflüger]*, 67, No. 9-10, pp. 371-449).—A number of experiments with dogs are reported.

**The function of pancreatic juice and of bile in the resorption of fat**, E. HÉDON (*Arch. Physiol. Norm. et Path.*, 5. ser., 9 (1897), pp. 622-634).

**On the digestibility and absorption of fat when a biliary fistula is made and the pancreas removed**, E. HÉDON and J. VILLE (*Arch. Physiol. Norm. et Path.*, 5. ser., 9 (1897), pp. 606-621).

**Changes in the form and position of the stomach of man during digestion**, A. BIANCHI and C. COMTE (*Arch. Physiol. Norm. et Path.*, 5. ser., 9 (1897), pp. 891-904).

**Absorption in the small intestine**, I. R. HÖBER (*Arch. Physiol. [Pflüger]*, 70, No. 11-12, pp. 624-642).—Experiments were made with dogs and rabbits on the absorption of solutions of a number of salts.

**The action of blood serum and a solution of propeptone on certain digestive ferments**, L. CAMUS and E. GLEY (*Arch. Physiol. Norm. et Path.*, 5. ser., 9 (1897), pp. 764-776).

**Experimental and critical studies of the feces of infants fed cow's milk and woman's milk**, M. BLAUBERG (*Experimentelle und kritische Studien über Säuglingsfäces bei natürlicher und künstlicher Ernährung*. Berlin, 1897; *abs. in Hyg. Rundschau.*, 8 (1898), No. 4, pp. 210, 211).

**On excessive nutrition**, G. PECORI (*Ann. Ig. Sper.*, u. ser., 6 (1896), No. 4, pp. 483-565).—A number of experiments with men on a mixed diet are reported, in which the food, urine, and feces were analyzed.

**Researches on organic phosphorus**, L. JOLLY (*Compt. Rend. Acad. Sci. Paris*, 126 (1898), No. 7, pp. 531-533).—The author reports investigations which lead to the conclusion that unoxidized phosphorus does not exist in tissue.

**The value of asparagin for Herbivora**, O. KELLNER (*Chem. Ztg.*, 21 (1897), No. 80, pp. 820, 821).—The author briefly reports results of a number of experiments conducted by Redner with lambs to determine the value of asparagin. Fifty grams of asparagin was substituted for 50 gm. of starch in wide and narrow rations. An experiment was also made in which 50 gm. of ammonium acetate was substituted for the same quantity of starch. The balance of income and outgo of nitrogen, and in some cases of sulphur, was determined. When asparagin and ammonium acetate were consumed the daily gain of nitrogen was larger than when this was not the case; that is, both substances served to protect protein. It was believed that this action was due to the fact that asparagin and ammonium acetate served as nitrogenous nutrients for the intestinal bacteria and so prevented the destruction of protein in the intestinal tract.

**The gaseous exchange and expenditure of energy of a bicycle rider**, L. ZUNTZ (*Arch. Physiol. [Pflüger]*, 70, No. 7-8, pp. 346-348).—A brief account is given of the author's experiments.

### DAIRY FARMING—DAIRYING.

**Feeding dairy cows**, C. D. SMITH (*Michigan Sta. Bul. 119, pp. 67–119, figs. 2*).—This bulletin consists of a popular discussion of the principles of feeding, calculations of rations, etc., with remarks on experiments in feeding the station herd. A record has been kept of the yields and amounts of the different kinds of feeding stuffs fed to the individual cows. While the general character of the ration was calculated beforehand, the quantity of both coarse fodder and of grain to be fed to the individual cows “was left entirely to the judgment of the man who fed the cows and who adjusted the quantity to the milk and the condition of the bowels.” The coarse fodder consisted principally of silage, with some clover hay, cornstalks, millet hay, roots, etc. The grain consisted of various mixtures of corn, oats, bran, linseed meal, cotton-seed meal, gluten meal, and occasionally other by products.

Analyses are given of the feeding stuffs mentioned, and of oat and pea silage, millet silage, Kafir corn silage, sorghum silage, lathyrus silage, lathyrus in full bloom, dried pasture grass, common millet seed, Hungarian seed, sorghum, and beans. The record of the cows for 3 winters is summarized, showing the amounts of the different kinds of food eaten per 1,000 lbs. live weight, the digestible food ingredients contained in the same, and the amount of butter fat produced per day. The cows are considered in 3 groups, *i. e.*, smaller cows, from 800 to nearly 1,200 lbs. in weight; larger cows, from 1,200 to 1,600 lbs., and cows nearly dry. The averages for each group of cows are summarized below:

*Food eaten and fat produced per 1,000 pounds live weight daily.*

	Food eaten.					Digestible nutrients in food.				Daily production of fat.
	Silage.	Mangel-wurzels.	Corn-stalks.	Hay.	Grain.	Dry matter.	Protein.	Carbo-hydrates.	Fat.	
	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.
Nine smaller cows..	29.82	12.85	1.00	3.29	14.12	23.57	2.06	12.50	0.89	1.21
Three cows nearly dry .....	32.75	.....	7.08	.33	6.23	15.20	1.09	8.20	.49	.23
Seven larger cows ..	34.75	18.41	.50	2.50	12.15	22.11	1.89	12.23	.67	1.03

These averages are “presented as a standard ration for Michigan conditions. . . . The nutritive ratio of the standard ration suggested for the thousand-pound cows is 1:7.1, that of the larger cows 1:7.21, and that of the cows in the very latest months of the period of lactation is much wider, being 1:8.53.”

The method of applying this standard in practice is discussed, and illustrations are given from the records of the cows to show that a

standard can not be rigidly adhered to, but must be modified by the feeder to suit the requirements and capabilities of different cows.

Popular notes are given on the various feeding stuffs used. The results of two-years' trials in ensiling clover "show that it is possible to ensile clover, that the silage keeps well, and that stock will eat it with evident relish. . . . [but] it is cheaper to allow the sun to dry the hay than to draw the green forage to the barn." A half acre of rape yielded at the rate of 2,678 lbs. of dry matter per acre. "The cows ate the rape silage with evident relish, and no taint was imparted to the milk by it." Further experiments will be necessary to establish the practicability of rape either as green fodder or as silage as a cow feed. A comparison of the yields per acre and cost of growing carrots, mangel-wurzels, and ruta-bagas is given.

*Effect of roots and potatoes on the digestibility of rations* (pp. 106-110).—The digestibility of a basal ration with and without mangel-wurzels or potatoes was studied with 2 cows. The basal ration consisted of 14.5 lbs. clover hay, 6 lbs. bran, and 6 lbs. corn meal. The results follow:

*Average coefficients of digestibility of rations with and without mangel-wurzels and potatoes.*

Period.		Dry matter.	Crude protein.	Fat.	Nitrogen-free extract.	Crude fiber.	Ash.
		<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>	<i>Per cent.</i>
1	Basal ration with 20 lbs. mangel-wurzels.....	66.19	60.54	71.74	74.18	51.36	48.17
2	Basal ration.....	64.14	60.27	79.12	71.42	48.73	43.97
3	Basal ration with 15 lbs. potatoes.....	63.24	56.71	65.32	73.33	38.92	47.40

"In passing from period 1 to period 2 it is evident that the removal of the beets from the ration decreased the digestibility of the dry matter, ash, crude fiber, and nitrogen-free extract, while the digestibility of the protein remained constant. The addition of potatoes to the ration still further decreased the digestibility of the dry matter of the crude fiber and markedly lowered the digestibility of the protein. This result is undoubtedly due to the fact that potatoes are nearly clear starch, and the addition of so much starch to a normal ration lowers the digestibility of the protein, the fat, and the crude fiber."

*Effect of potatoes and roots on the quality of the butter* (pp. 110-116).—This was studied with 5 cows in periods of about 3 weeks, the results being compared with those on dry feed. The average time required for churning was 34 minutes when on dry feed, 36 minutes when on mangel-wurzels, and 86 minutes when on potatoes.

"On this point there was a very marked difference due to the feeding of potatoes. The cream frothed badly in the churn and it took more than twice as long to bring the butter. . . . No important difference is noted in the composition of the butter that could be ascribed to the potatoes. In one case the butter was much harder where the cows had the potatoes, in another it was as soft as when the cows were on dry feed. The per cent of volatile fatty acids, the ingredients that give butter its characteristic flavor, was slightly higher on the average in the potato butter than in the butter from dry feed."

Brief mention is made of experiments in two successive winters to test the effect of gluten meal on the quality of butter.

“It was found as an invariable result that the gluten meal made the butter softer and made it difficult to so churn the cream as to extract all of the butter from the buttermilk. The per cent of fat in the buttermilk invariably increased from 0.1 per cent to 6.25 per cent, or even 0.5 per cent when gluten meal was fed.”

The data are given of a study of the difference in composition of burr and roller process wheat bran, showing that “the roller-process brans are all perceptibly higher in protein than those of the burr-stone process.”

*Dairy barn* (pp. 116-119).—A description is given of the new dairy barn built at the station in 1887. The barn is 45 by 70 ft., accommodates 30 cows, and cost \$737.

**Further investigations on the milk production of goats**, KOHL-SCHMIDT (*Landw. Jahrb.*, 26 (1897), No. 4-5, pp. 783-802).—The author reports investigations on the yield and fat content of 16 Swiss goats, 11 native goats, and 4 crosses between the native and Swiss goats. The observations extended over a number of months. The yield and fat content of the milk from each of the 3 milkings daily are tabulated in detail.

With the Swiss goats the annual milk yield ranged from 421.91 to 911 liters, averaging 678.41 liters per head. The fat content of the milk of the 3 to 4 year old goats averaged 3.6 per cent, and of the younger animals 2.79 per cent for the entire period of lactation. The native goats gave from 674.72 to 1,255.44 liters of milk during the year, the average being 877.88 liters. The fat content ranged from 2.49 to 3.76 per cent, and averaged 3.07. The goats were milked 3 times daily. The milk from the noon milking was nearly always the richest in fat, and that from the morning's milking the poorest.

**The source of milk fat**, W. H. JORDAN and C. G. JENTER (*New York State Sta. Bul.* 132, pp. 457-488).—In this experiment a cow was fed for 2 weeks on normal food and then for 95 days following on a food from which the fat had been extracted as thoroughly as was possible. The milk was analyzed for 102 days; the urine and feces were collected and analyzed for 66 days, this being done continuously during 59 days of the time in which extracted foods were fed. A young grade Jersey cow, somewhat thin in flesh and about 4 months advanced in the period of lactation when the experiment was begun, was used. The food consisted of timothy hay, corn meal, and wheat gluten, the latter containing from 72 to over 74 per cent of protein. These foods were extracted by an oil company, and although repeated treatment failed to remove the fat entirely, the amount was so small that a fairly generous ration contained not over 0.13 lb. of ether extract per day.

“It is a matter of congratulation that the regular consumption of the rations was accomplished with a very satisfactory degree of success, considering the conditions under which the experiment was carried on. The health of the animal did not appear to be impaired by the food and treatment which she received.”

The rations were varied at different times so as to furnish different amounts of air-dry food material and different amounts of protein, the decrease in protein being accompanied by an increase of carbohydrates.

The full data for the experiment are tabulated showing the composition of normal and extracted foods; the amount of food eaten; the composition of the milk, urine, feces, etc., and from these data the amounts of nitrogen and of fat consumed and extracted are calculated. Incidentally some data are given as to the comparative results of extraction of fat with sulphuric and petroleum ethers and the effect of drying upon the nitrogen content of cows' feces. The results as to the income and outgo of nitrogen and fat are summarized in the following tables:

*Income and outgo of nitrogen.*

Period.		Income.		Outgo.				Daily gain (+) or loss (-) of nitrogen.	
		Days in period.	Total nitrogen in food.	Nitrogen digested.	Nitrogen in milk.	Nitrogen in urine.	Nitrogen in feces.		Total outgo of nitrogen.
	<i>Nitrogen balance.</i>

<sup>1</sup>The urine contains no fat.

Among the author's conclusions are the following:

"(1) A cow fed during 95 days on a ration from which the fats had been nearly all extracted continued to secrete milk similar to that produced when fed on the same kinds of hay and grain in their normal condition.

"(2) The yield of milk fat during the 95 days was 62.9 lbs. The food fat eaten during this time was 11.6 lbs., 5.7 lbs. only of which was digested; consequently at least 57.2 lbs. of the milk fat must have had some source other than the food fat.

"(3) The milk fat could not have come from previously stored body fat. This assertion is supported by three considerations: (1) The cow's body could have contained scarcely more than 60 lbs. of fat at the beginning of the experiment; (2) she gained 47 lbs. in body weight during this period of time with no increase of body nitrogen, and was judged to be a much fatter cow at the end; (3) the formation of this quantity of milk fat from the body fat would have caused a marked condition of emaciation, which, because of an increase in the body weight, would have required the improbable increase in the body of 104 lbs. of water and intestinal contents.

"(4) During 59 consecutive days 38.8 lbs. of milk fat was secreted and the urine nitrogen was equivalent to 33.3 lbs. of protein. According to any accepted method of interpretation, not over 17 lbs. of fat could have been produced from this amount of metabolized protein."

As to the source of milk fat, the conclusion is reached that in these experiments the milk fat "was produced, in part at least, from carbohydrates, as previous experiments have demonstrated to be the case with body fat."

It is pointed out that, while the German standard calls for 2.5 lbs. of protein per day, an average yield of 30 lbs. of milk would not contain over 1 lb. of protein, leaving 1.5 lbs. of protein unused, so far as known, for necessary constructive purposes. It is shown that—

"The quantity of milk solids secreted bore a definite relation neither to the digestible protein eaten nor to the extent of the protein metabolism. . . . The extent of protein metabolism seems to be influenced mainly by the protein supply rather than by the quantity of milk solids secreted. . . .

"We desire to propose as a rational explanation of the notable influence upon milk secretion of an abundant supply of digestible protein in the ration that it is due to the influence of protein upon metabolic activity rather than because so much was needed from which to form milk solids. This view would not minimize our estimate of the importance of the nitrogenous constituents of cattle foods, but simply emphasizes more fully one reason, and perhaps the main one, why they should be supplied in such generous proportions.

"[As to the composition of the milk], this bore no definite relation to the amount and kind of food.

"Neither a deficiency in the protein of the ration nor a depression of the digestible nutrients to about 55 lbs. per day caused the cow to produce poorer milk. The only apparent effect was in changing the quantity of product. . . .

"The changes in the proportion of milk solids were due almost wholly to changes in the percentage of [milk] fat."

**Investigations on the composition of colostrum and the change to normal milk**, F. G. DEISSMANN (*Inaug. Diss., Heidelberg, 1897, pp. 98*).—The author introduces the account of his investigations with a quite thorough review of work previously published on the subject. His investigations were made on 3 cows and 2 sheep. Complete analyses were made of the milk immediately after calving and at short intervals,

usually four hours, for several days, after which the analyses were continued at longer intervals for some time. In addition to analyses, the physical properties of the samples, behavior toward rennet and toward heating, etc., were noted.

In the case of 1 cow (North Ditmarsh)  $5\frac{1}{2}$  kg. of colostrum was milked seven hours before calving to relieve the cow. It had a red color and contained numerous blood corpuscles. Immediately after calving the colostrum was a yellowish brown color, and no blood corpuscles could be recognized.

A portion of the analyses of the cow's milk for the first four days after calving are given below.

*Analyses of colostrum of three cows.*

	Total solids.	Fat.	Nitrogen.			Total albuminoids. <sup>1</sup>	Ash.

<sup>1</sup> Albuminoid nitrogen  $\times$  6.37.

<sup>2</sup> Fat determinations lost.

There appeared to be no characteristic relationship between breed and the composition of the colostrum. The greatest change in the colostrum took place within the first few hours after calving. It gradually became like normal milk, which it resembled in outward appearance and in its behavior toward rennet and toward heating, in from three to four days, although not constant in composition until several days later. The colostrum of the Dutch cow differed from that of the others in giving an amphoteric reaction 12 hours after calving, while that of the other cows was acid for the first three or four days. In no case did the colostrum have an unpleasant odor or taste, and this was true of the colostrum of 8 other cows which was tested.

The colostrum contained considerable quantities of nonalbuminoid nitrogen, which diminished after a day or two, although small quantities were found in the normal milk. It is believed to have consisted principally of urea, although amids may have been present also.

The colostrum from the sheep contained more casein than albumin and did not contain nearly as much total albuminoids as that from cows. It contained some nonalbuminoid nitrogen, the amount of which was not uniform. Small amounts of lactoprotein and lactoglobulin were detected. Like the colostrum from cows, sheep's colostrum had no characteristic taste or odor.

**Some conditions affecting churning with churns of different construction,** E. J. VON STOCKHAUSEN (*Inaug. Diss., Leipsic, 1897, pp. 87*).—Following a review of the literature, the author reports 90 experiments with four different churns. These were (1) the Davis Swing churn; (2) the Saxonia churn—a revolving square churn with dasher arrangement, (3) the Victoria churn—an ordinary barrel churn—and (4) the Holstein churn—a stationary churn with dasher. The experiments were made in the experimental creamery of the university. The milk used was mixed milk of quite constant composition. The cream was separated in a hand separator and after testing for fat was made to a constant content of 20 per cent of fat by the addition of skim milk. In about half the cases the cream was churned sweet, and in the balance of the cases it was ripened for 24 hours, showing about 30° of acidity with decinormal soda solution. The experiments were also varied in the amount of cream placed in the churn and in the temperature of the cream at the beginning of churning. The full data for each experiment as to amount and composition of the cream, buttermilk, and butter; the temperature; time required for churning, and percentage of churnability are tabulated. No averages are given, but the best results obtained with the four different churns are summarized as follows:

*Best results with different churns.*

	Experiment No.	"Fullness" of churn.	Temper-	Time	Churn-ability.
			ature of cream.	of churning.	
			° C.	Min.	Per ct.
Davis Swing churn, sour cream .....	15	1 1/4	16	25	97.75
Do .....	16	1 1/4	16	25	97.96
Saxonia churn, sour cream .....	37	1 1/4	14	50	98.35
Do .....	38	1 1/4	14	48	98.31
Victoria churn, sweet cream .....	49	1 1/4	10	70	99.25
Do .....	50	1 1/4	10	65	98.51
Victoria churn, sour cream .....	65	1 1/4	14	57	98.12
Do .....	66	1 1/4	14	57	98.10
Holstein churn, sour cream .....	85	1 1/4	16	35	99.27
Do .....	86	1 1/4	16	30	95.28

The author concludes that on the whole the Holstein churn gave the best results, although he states that usually a smaller relative amount of cream was churned in the Holstein churn than in the Victoria. He concludes further that: (1) Sour cream churns more rapidly than sweet cream and gives the larger yield of butter. (2) The time required for churning varies with the amount of cream in the churn ("fullness"). With an increase in the amount of cream there is an increase in the churnability until the optimum is reached, beyond which the time required for churning increases and the churnability diminishes. (3)

Increasing the temperature of the cream at the beginning of churning decreases the time required for churning, but usually also decreases the churnability.

While the time required for churning sweet cream in the Holstein and Saxonia churns was very unfavorable, with the Davis Swing and Victoria churns sweet cream could be churned quite rapidly, provided only a limited quantity of cream was churned at once. With the latter churns the churnability of sweet and sour cream were approximately the same. The sour cream usually gave a butter of better appearance than sweet cream, although the sweet-cream butter usually had a more delicate flavor. The quality of the butter suffered specially when the cream was too sour, as more casein was incorporated into the butter, which affected its keeping quality.

Regarding the second point, attention is called to the amount of cream which can be satisfactorily churned in a churn, beyond which the time required for churning increases and the completeness of churning decreases. As a rule, filling the churn from  $\frac{1}{4}$  to less than  $\frac{1}{2}$  full gave the best results. The churning was rapid and complete with sweet cream only when a small amount of cream was used, but the results were satisfactory with sour cream when the churn was  $\frac{1}{3}$  full. The churnability began to decrease when the churn was  $\frac{2}{3}$  full in the case of the Saxonia,  $\frac{1}{2}$  full in the case of the Holstein, and  $\frac{1}{5}$  full in the case of the Victoria churn. An increase in the temperature at the beginning of churning diminished the time required for churning, but diminished the yield of butter also. Furthermore, an increase in the temperature of sweet cream caused soft butter.

In conclusion, remarks are made on the construction of the different churns and their adaptability to different purposes.

## VETERINARY SCIENCE AND PRACTICE.

Report on the results of the investigations by the commission for the study of the foot and mouth disease at the Institute for Infectious Diseases at Berlin, LOEFFLER and FROSCHE (*Centbl. Bakt. u. Par.*, 1. Abt., 22 (1897), No. 10-11, pp. 257-259).—According to this report the bacteria hitherto found and considered to be the cause of the disease are accidental. A protozoan element, not the Sigel Bussenius bacillus, seems to be the cause. Cattle and swine are especially susceptible, while sheep, goats, dogs, guineas, house and field mice, and birds are not subject to artificial infection with lymph containing this element. Lymph from the vascular tracts affords the surest means for infection by injection into peritoneal cavities or into muscles, as also by rubbing on abraded mucous membranes. In animals injected intravenously fever appears in from one to three days, according to the amount and the virulence of the lymph. Blisters appear first in the mouth (in milk cows also on the udder) and in from one to two days later on the feet. The blisters on the udder and the feet arise not from external infection, but from the virus circulating in the blood. When they appear the virus disappears from the vascular tracts.

For the purpose of injection 1/5,000 cc. of fresh lymph is sufficient, smaller amounts, to 1/20,000 cc., are uncertain, and anything smaller than 1/20,000 cc. is inoperative. The infective properties of the lymph are destroyed by heating for twelve hours at 37° C. or at 70° C. for half an hour, or by drying for twenty-four hours at summer temperature. Kept in capillary tubes in an ice chest it retains its powers for fourteen days, sometimes longer.

Contrary to the published views of veterinary authorities, in the greater number of affected animals sickness brings about immunity in from two to three weeks after their becoming sick. Some animals are naturally immune, others are very susceptible and become immune only after a second illness.

Some substance occurs in the blood of immune animals injected with fresh lymph that renders the lymph powerless when mixed with the blood of such animals and injected into susceptible animals.

Cattle and swine may be made immune by inoculation with such a mixture or by lymph warmed to the proper infecting point. Most animals require but one injection, and this may not apparently make the

animal sick. The final conclusion of the commission is that it seems absolutely certain that the foot and mouth disease can be successfully combated by means of inoculation.

**Report of the veterinary service and meat control in Norway for 1895.** O. MALM (*Ber. om Veterinär-råsenet og Kjødkontrollen i Norge, 1895, Norges Offic, Statistik, Række 3, No. 270. Christiania, 1897, pp. 203*).—This report has a résumé in French.

The only part of the report of general interest is that describing the results of the tuberculin tests conducted since the spring of 1895 under the auspices and at the expense of the Norwegian Government. All owners of cattle who agree to comply with the regulations prescribed for the control of bovine tuberculosis are entitled to have their cattle tested free of charge. The sum of 10,000 kroner (\$2,680) was appropriated to defray the expenses of the tuberculin tests in 1895-'96, and for the two following years 15,000 (\$4,020) and 18,000 kroner (\$4,824) were appropriated. The main results of the investigations are given below.

Up to date 2,195 different herds, aggregating 30,787 head of cattle, have been examined. Of these 8.4 per cent were found to be tuberculous and 26.1 per cent reacted under the tuberculin test. In the majority of herds only individual cases were found, and these, almost without exception, were recently purchased animals. The results show that in comparison with other European countries where similar statistics are available, and particularly in comparison with Swedish, Danish, and German cattle, tuberculosis is not so prevalent among the cattle of Norway. The results of the examination are given in the following table:

*Distribution of bovine tuberculosis in Norway.*

	Breeds.					Ages.				
	Native.	Tele-mark.	Ayr-shire.	Mixed.	Miscellaneous.	Under 6 mos.	6 mos.-1 year.	1-5 years.	Over 5 years.	Age not given.
Total number examined .....	13,548	2,174	692	13,506	867	1,551	2,237	13,179	13,449	371
Percentage tuberculous .....	6.8	6.1	18.4	10.4	7.2	1.0	3.4	7.9	10.3	18.9

The veterinarians making the tests reported repeatedly that consumption in man was found, or had been found, on farms where bovine tuberculosis was shown to be present.

The laws and regulations governing tuberculin tests, meat control, and other branches of the veterinary service are given in the report.—F. W. WOLL.

**Powdered soap as a cause of death among swill-fed hogs.** V. A. MOORE (*New York Cornell Sta. Bul. 141, pp. 409, 418*).—An account is given of a series of experiments in feeding pigs with powdered soaps such as are used in washing dishes, etc., in hotels, and which eventually find their way into swill barrels.

According to the analyses made by G. W. Cavanaugh, the assistant chemist, these soaps contain from 49.6 to 55.04 per cent of sal soda. When the soap was fed to pigs in amounts varying from  $\frac{1}{2}$  to 5 oz. per day they became sick and showed all the symptoms that had been observed in hogs fed upon swill that contained soap in greater or less amount. Diarrhea was a constant symptom. In severe cases there was much difficulty in standing and the muscles of the head and legs were more or less constantly jerking. Connected with these symptoms there was a loss of appetite. Where the pigs recovered from the immediate effects they did not become thrifty for some weeks. A post-mortem examination of those that died showed the skin between the thighs to be of a pinkish color, kidneys pale, the blood vessels of the mesentery much congested, the mesenteric glands enlarged and œdematous, many congested, the mucous membrane of the intestines of a dark reddish color, the brain very much congested, and the mucosa of the stomach covered with a thick layer of mucus.

Bacteriological examinations brought to light no evidence of bacteria. Check experiments were made. In conclusion, it is noted that the greatest amount of loss from swine disease in the State is among hogs fed on swill collected from hotels, boarding houses, and other large institutions; that the cause of the death in certain outbreaks among such swill-fed hogs is due to the poisoning of the animals by an excess of free alkali in the swill. Small quantities of the powdered soaps produced no immediate bad results, but it is not safe to feed them to animals. The proper channel for the disposal of dish water is the sewer.

**Cashew [mesquite] poisoning**, WILLIAMS (*Jour. Jamaica Agr. Soc.*, 1 (1897), No. 9, pp. 319-321).—When animals are fed with this legume (*Prosopis juliflora*) they become slick, glossy, and look well. The animals seem very fond of it. But when it is damaged by rains, heavy dews, etc., it is poisonous. Animals that eat it when it is in the poisonous condition become distended with gas and rupture of the digestive system may result. Clots of blood have been found in the cerebellum. The first symptoms are colicky pains with abdominal distension; the animal paws, lies down and rises frequently, and shows an inclination to thrust its head into corners. It may lie on its back with feet doubled up and groan with pain. Cold sweats occur, breathing becomes thick and labored, and there are frequent attempts at micturition. Urine is voided in small quantities. The remedy is puncturing the abdomen and drawing off the gases, together with hot fomentations to abdomen and loins and the administration of oil and hot water enemas. The animal may finally die from collapse.

**On Drepanidotænia hemignathi, a new species of tapeworm**, A. E. SHIPLEY (*Quart. Jour. Micros. Sci.* [London], n. ser., 40 (1898), No. 4, pp. 613-623, pl. 1).—This species is based on ten specimens from the intestine of *Hemignathus procerus* from the Sandwich Islands. It varies from 1 to 2.2 cm. in length and at the middle of the body is 2 mm.

broad. The head is provided with a row of ten hooks each from 18 to 23 $\mu$  long. The segmentation begins close behind the head, having scarcely any neck. The genital pores are unilateral. Eggs, spherical, 40 to 50 $\mu$  in diameter.

In the length of the hooks the species resembles *D. tenuirostris* in which they are 20 to 23 $\mu$  long. In the embryo of *D. hemignathi* the hooks are 20 $\mu$ ; in the embryo *D. tenuirostris* only 7 $\mu$ . The species differ further in the longer neck in the last-named form and in its larger egg.

On the "leucocide" substances in the metabolic products of *Staphylococcus pyogenes aureus*, O. BAIL (*Arch. Hyg.*, 32 (1898), No. 1-2, pp. 133-171).

Researches on the influence of the organism on toxins, E. METCHNIKOFF (*Ann. Inst. Pasteur*, 11 (1897), No. 11, pp. 801-809).—The author concludes that plants such as bacteria and fungi can destroy toxins and transform them into vaccines without producing an antitoxin; that the invertebrates are capable of producing a tetanic antitoxin in appreciable quantities; that the production of antitoxins begins in the animal series with the crocodiles, where the power is more highly developed than in the higher animals; that the antitoxic power is not to be considered as bound to any febrile reaction whatever; that the antitoxic property of the fowl is in the blood; that it is not possible to accept the idea that natural immunity depends on the antitoxic power, and that the antitoxic property in the animal kingdom has an evolution less ancient than the phagocytic reaction.

Helminthological contributions, A. MÜLLER (*Arch. Naturgesch.*, 63 (1897), pp. 1-26, pls. 3; abs. in *Zool. Centbl.*, 5 (1898), No. 2, pp. 49).—A description is given of *Spiroptera truncata* Crpl., from *Coriacias garrula*, and of *Filaria capitellata* Schn., which is regarded as identical with *Hystrichis papillosa* Rud., from *C. garrula*. *Dispharagus anthuris* of Rudolphi, Molin, and Dujardin is to be separated from *F. anthuris* of Schneider and von Linstow; the name of the latter must be retained, while the former species, which is found between the gastric membranes of *Lanius collurio*, *L. rufus*, and *Coracias garrula*, must be called *Dispharagus cordatus*. There are also described: *F. recta* v. Linst., from *Podiceps cristatus*; *F. involuta* v. Linst., from *Egolius otus*; *F. tricuspidis* Fedt., from *Corvus corone*: an unknown *Ascaris* from the oesophagus and stomach of *Felis tigris*; *Heterakis compar* Schrank, from *Tetrao urogallus* and *T. tetrix*; *Ankylostomum trigonocephalum* Rud., from *Canis vulpes*; *Strongylus nodularis* Rud., from *Fulica atra*; *S. retortaformis* Rud., from *Lepus*; *Crenosoma semiaratum* Molin, from *Canis vulpes*; and *Ancerjancanthus bihamatus* n. sp., from *Sterna risoria*.

Pecundation in *Ascaris megaloccephala*, J. B. CARNOY and H. LEBRUN (*Cellule*, 13 (1897), pp. 69-155, pls. 2; abs. in *Zool. Centbl.*, 5 (1898), 3, pp. 79-84).

Contributions to the structure of protoplasm, the karyokinetic spindle, and the centrosome. I, On the fertilization and first division of the egg of *Ascaris*, R. VON ERLANGER (*Arch. Mikros. Anat.*, 49 (1897), pp. 309-440, pls. 3; abs. in *Zool. Centbl.*, 5 (1898), No. 3, pp. 74-79).

The genus *Ascaris*, M. STOSSICH (*Il genere Ascaris Linné. Trieste, 1896, pp. 114*).—A taxonomic description is given of 217 species. Their synonymy seems to be fully brought out, and hosts and localities are usually mentioned. In the systematic index given the parasites are noted under the names of their hosts arranged in zoological order. From this it appears that 77 species of mammals, 170 of birds, 37 of reptiles, 5 of amphibians, 142 of fishes, and 1 of insects are affected.

The single insect host is *Pterostichus niger*, which harbors *Ascaris pterostichi*.

*Bothriocephalus zschokkei*, M. LÜHE (*Zool. Anz.*, 20, No. 544, pp. 430-434; abs. in *Zool. Centbl.*, 5 (1897), No. 2, p. 47).—*Bothriocephalus zschokkei* is thought synonymous with *Schistocephalus dimorphus*.

A preliminary contribution on the anatomy of *Tænia polymorpha*, K. WOLFFHUGEL (*Zool. Anz.*, 21, No. 554, pp. 211-213).—The testis, vas deferens, and cirrus apparatus are paired; the female genital glands and the uterus simple; the vagina

does not communicate with the outer world: the cirrus bores directly into the parenchyma, breaking through the cuticula at places that are not predetermined.

These facts are thought to be of sufficient weight for the creation of a genus, but this is deferred until the relationships are considered in a later paper.

On the œsophagus of nematodes, especially of *Strongylus armatus* and *Dochmius duodenalis*, L. A. JÄGERSKIÖLD (*Bihang Svenska Vetensk. Akad. Handl.*, 23 (1897), II, No. 5, pp. 1-26, pls. 2; *abs. in Zool. Centbl.*, 5 (1897), No. 2, p. 48).—The author finds that the glands in the dorsal side of the œsophagus in *Strongylus armatus* and *Ankylostomum duodenale* open into the oral cavity at its anterior end.

The strongylus of the sheep's stomach, C. JULIEN, (*Jour. Agr. Prat.*, 1 (1898), No. 4, pp. 137-141, figs. 5).—The affected animals are caused to drink a glass of water with some linseed oil in which there is mixed at the moment of administration 5 to 6 cc. of benzine for lambs or 6 to 8 cc. for sheep. If the animal is very sick the dose should be graduated, beginning with 2 to 3 cc.

*Bothriotænia chilensis*, n. sp., E. RIGGENBACH (*Actes Soc. Sci. Chile*, 7, (1897), pp. 66-73, pl. 1; *abs. in Zool. Centbl.*, 5 (1897), No. 2, p. 47).—This new species was taken from *Geomyxerus chilensis* and reaches a length of 5 cm. The scolex bears 2 flask-like independent bothridia. The genital pores lie irregularly and alternatingly on both sides of the body, the uterus opening on the ventral surface of the proglottid. The body surface is covered with pores of fine and numerous excretory vessels.

The development of the sporozoa of the genus *Coccidium*, P. L. SIMOND (*Ann. Inst. Pasteur*, 11 (1897), No. 6, pp. 546-581, pls. 2).—By means of experiments on rabbits and on *Salamandra maculata* and by microscopical observations the author has found that *Coccidium oriforme* and *C. (Karyophagus) salamandra*, instead of being dimorphic in their cycle of development, are polymorphic. What applies to this applies with slight modification also to *C. proprium* and, in all probability, to the rest of the genus.

New worms from Eritrea, E. SETTI (*Atti Soc. Ligust. Sci. Nat. e Geogr. Genova*, 8 (1897), pt. II, pp. 1-51, pls. 2; *abs. in Zool. Centbl.*, 5 (1898), No. 2, p. 49).—The new form *Oxyuris stossichii* from the intestine of *Hystrix cristata* is described.

Tuberculosis in cattle (*Ontario Dept. Agr., Spec. Bul.* 1897, July, pp. 12, pls. 2).—This is a popular bulletin designed to awaken the attention of Canadian cattle breeders to the widespread existence of tuberculosis, giving popular directions for testing suspected animals, enumerating the utensils used in making the tests, and stating where the instruments may be obtained.

## TECHNOLOGY.

**Beet sugar production in Sweden** (*Tidskr. Landtmän*, 18, No. 6, pp. 96-99).—The total quantity of beets worked during the campaign of 1895-'96 was 535,149.4 tons. The products obtained were 54,822.41 tons first sugars, 5,371.86 seconds, 1,920.61 thirds (total, 62,114.88 tons), and 15,753.4 tons of molasses. The amount of sugar obtained was 11.75 per cent and that of molasses 2.94 per cent of the tonnage of beets. The average content of polarized sugar in the beets was 13.45 per cent, the range in the average per cent for all factories being from 12.18 to 14.51 per cent. The average sugar content in single factories ranged between 9.3 and 15.8 per cent.

The factory at Roma, Gotland, which is largely, if not entirely, supplied by beets grown on marsh soils, received the richest beets. The average content of sugar in the beets was 15 per cent, the percentage ranging from 14.5 to 15.8. The yield of sugar was 12.75 per cent and that of molasses 3.02 per cent of the tonnage of beets worked.

The following comparative statistics are considered of interest in this connection:

*Beet sugar production in Sweden, Germany, and France, 1891-'96.*

Campaign.	Sweden.			Germany.			France.		
	No. of factories.	Average quantity of beets worked.	Yield of crude sugar from beets.	No. of factories.	Average quantity of beets worked.	Yield of crude sugar from beets.	No. of factories.	Average quantity of beets worked.	Yield of crude sugar from beets.
		Tons.	Per cent.		Tons.	Per cent.		Tons.	Per cent.
1891-'92. ....	8	32,509	10.26	403	23,543	12.06	368	15,287	11.41
1892-'93. ....	10	27,745	10.80	401	24,468	11.94	367	14,872	10.62

<sup>1</sup>At 3 of the factories only the juice was extracted, which was then sent to the other factories for the remaining processes of manufacture.

—F. W. WOLL.

**An experiment in generating vinegar,** W. B. ALWOOD (*Virginia Sta. Bul. 71, pp. 123-128*).—This is a continuation of the work reported in Bulletin 57 of the station (E. S. R., S. p. 977). The object of the work was "to determine the feasibility of manufacturing vinegar by modern methods on the average farm." The vinegar generator used consisted of a 4 by 8 ft. wooden tank filled with beech shavings. The tank was provided with holes near the bottom for the admission of air, and fitted 1 ft. from the top with a wooden disk perforated to allow the entrance of the cider, which was distributed evenly over it by means of a dumper. The vinegar was drawn from the tank by means of a siphon of glass tubing inserted in a hole near the bottom. The temperature of the fermenting cider in the mass of shavings was controlled by regulating the supply of air, some of the air holes being shut off when the temperature rose too high and opened when it fell too low.

In order to acidify the shavings and start the process of fermentation, the generator was charged with strong vinegar and again with vinegar in which some concentrated grape juice was dissolved. The stock solution, a mixture of weak vinegar and fermented cider, was then run through the generator at the rate of 20 gal. per day (24 hours). The resulting product was a very good vinegar, ranging from 4.05 to 5.87 per cent acid. A mixture of half vinegar and half fresh cider failed to produce good vinegar without being run through the generator twice. Better results were obtained by allowing the cider to ferment for some time in casks before running it through the generator. The temperature within the generator 2 ft. from the bottom ranged from 88 to 106°. The higher temperature caused a loss of alcohol and lowered the acidity of the product. Temperatures below 90° did not give good results. The optimum is thought to be about 95°.

It is believed that this method of manufacturing vinegar might be used with considerable profit if it were not for the cheap vinegars made

as by-products from various factories and colored and flavored to imitate cider vinegar.

**On the manufacture of potato starch**, M. J. KJUS (*Tidsskr. Norske Landbr.*, 4 (1897), No. 5, pp. 203-208).—The process is described and the machinery illustrated.

**Hydromel**, G. DE LAYENS (*L'Hydromel. Paris: Paul Dupont, 1894, pp. 20, figs. 3*).—A brief pamphlet discussing the various questions connected with the making of hydromel. It is estimated that hydromel is worth 1½ francs per liter; and since about a pound of honey is required to make each liter, deducting the expense of fermentation, etc., it raises the price of honey to about 75 centimes per pound. The formula for making hydromel is water 75 liters, honey 25 liters, tartaric acid 50 grams, bismuth 10 grams, fresh pollen 50 grams.

**Contribution to the study of oxydase of grapes—its utility in vinification**, A. BOUFFARD and L. SEMICHON (*Compt. Rend. Acad. Sci. Paris, 126 (1898), No. 5, pp. 423-426*).

**Wine making**, M. BLUNNO (*Agr. Gaz. New South Wales, 9 (1898), pt. 1, pp. 1-31, pl. 1, figs. 17*).

**The preparation of white wines from red grapes**, V. MARTINAND (*Compt. Rend. Acad. Sci. Paris, 126 (1898), No. 9, p. 656*).

**Concerning so-called boiled wine (vini cotti)**, G. PARIS (*Ztschr. Untersuch. Nahr. u. Genussmtl., 1898, No. 3, pp. 164-167*).—Analyses of a number of samples are reported.

**The temperature of wine fermentation**, L. ROOS (*Prog. Agr. et Vit., 29 (1898), No. 12, pp. 358-363*).

**The discoloration of wine (la casse des vins)**, A. BOUFFARD (*Ann. École Nat. Agr. Montpellier, 9 (1895-'96), pp. 197-212*).—The author classifies the changes which the coloring matter of wine undergoes, all of which have been more or less confused. As defined by him they are (1) the decomposition of the coloring matter through bacterial agencies; (2) the bluing of wines due to the chemical oxidation of certain wines; (3) the precipitation of coloring matter due to chemical action; and (4) the rapid oxidation and precipitation of the coloring matter through chemical changes induced by the presence of the ferment, oxydase.

The latter class alone should be considered under the name "la casse des vins." In this class of change, heating the wine to 65 to 70° C., or sulphuring, will, to a great degree, prevent the discoloration.

**The microorganisms of the brewing industry**, A. JÖRGENSEN (*Die Mikroorganismen der Gärungsindustrie. Berlin: Paul Parey, 1898, 4. ed., pp. VIII, 349, figs. 79*).

**On the olive oil of Dauro, Portugal**, A. J. FERREIRA DA SILVA (*Bul. Soc. Chim. Paris, 3. ser., 19 (1898), No. 2, pp. 88-90*).

**Peanut oil and its uses in pharmacy and the arts**, S. P. SADTLER (*Proc. Amer. Pharm. Assoc., 45 (1897), pp. 179-182*).—The successful substitution of peanut oil for olive oil in some pharmaceutical preparations is reported.

## AGRICULTURAL ENGINEERING.

**Report of the section of meteorology and irrigation engineering**, L. G. CARPENTER (*Colorado Sta. Rpt. 1897, pp. 62-85, 93, 94, 106-108, figs. 4*).—A summary is given of the work of this department of the station during the year in the measurement of return waters from irrigation, evaporation from reservoirs, water available for irrigation in different streams, the rise and fall of water in streams, with fluctuations in rainfall and temperature, duty of water on farms, observations on ground water, duration of sunshine, measurements of solar energy, soil temperatures, atmospheric pressure, etc.

Measurements of return waters from irrigation in the same line as those of previous years<sup>1</sup> were made in 1897 on the Big Thompson and its tributary, the Little Thompson, the Rio Grande, and the Cache la Poudre. The measurements on the Rio Grande showed that the return of water to that stream is small, but for a portion of its length it is losing a large amount of water from its bed. For 10 miles of its course this loss was found to amount to from 75 to 100 cu. ft. per second. Measurements on the Cache la Poudre indicate that the losses are not large enough to justify the use of any means of saving the water. The Big Thompson and the Little Thompson showed a gain of 70 cu. ft. per second from return water. Since these gains of the streams must be due at least in part to losses from canals, measurements were undertaken along about 70 miles of canal to ascertain the losses from seepage. Losses were found in different canals varying from "a depth of 1 ft. in 24 hours over the canal surface to a depth of over 20 ft. in the same time. The average loss of canals in good condition may be put provisionally at 2 ft. in 24 hours."

Observations were made on the amount of evaporation from the surface of a number of lakes, which indicated that the loss from this source was over one-half greater than that recorded in a standard evaporation tank in the college grounds, which was 41 in.

The amounts of water furnished by the Cache la Poudre River during the year, as recorded by a self-registering instrument placed at the point where the river flows out of the mountains and above all the ditches except one, were reported in weekly bulletins, which were supplied to the local press, "so that the irrigation interests should know something of the stage of water and of the probable changes to be expected." The instrument used in recording the water supply in the river is described. In connection with the river records rainfall stations were maintained at various places in the mountains, and in a few places temperature observations were made. These observations promise to be of considerable value in predicting the rise of water in different mountain streams.

The amounts of water used for irrigation on certain farms were recorded as in previous years, and observations have been made on the fluctuation in the level of ground water. Investigations on the water supply, especially the artesian water of the San Luis Valley, were continued in 1897. It is believed that this valley was the bed of an ancient lake, or rather of two lakes at different periods. This explains why a portion of the valley is water-logged, and also why certain of the shallower artesian wells furnish water which is unfit for drinking purposes. A contour map has been prepared which shows that the water-logged soils can be drained, and it is explained that pure water may be obtained by sinking the artesian wells through the second lake bottom, and casing the wells to keep out the water from the upper strata.

---

<sup>1</sup> Colorado Sta. Bul. 33 (E. S. R., 7, p. 898).

The meteorological records are not reported in detail. They included observations on temperature and pressure, evaporation, rainfall, humidity, sunshine, and solar intensity made at the station, substations, and by voluntary observers at different points in the mountains.

**Some notes on draining**, H. V. JACKSON (*Agr. Gaz., New South Wales*, 8 (1897), No. 12, pp. 881-893, figs. 25).

**Report on trials of farm machinery**, U. SVERDRUP (*Tidsskr. Norske Landbr.*, 5 (1898), No. 1, pp. 5-47, ill.).—The report gives full descriptions of trials of 7 self-binders and 10 potato harvesters conducted at Aas and Storhamar, Norway, during the fall of 1897, under the direction of the Society for Norway's Weal.

**Preliminary results of trials of self-binders at Aas Agricultural College, 1897** (*Tidsskr. Norske Landbr.*, 4 (1897), No. 10, p. 432).

**Preliminary results of trials with potato harvesters**, U. SVERDRUP (*Tidsskr. Norske Landbr.*, 4 (1897), No. 10, p. 472).

**Repairs of macadam roads**, E. G. HARRISON (*U. S. Dept. Agr., Office of Road Inquiry Circ.* 30, pp. 14).—The text of a paper and letters from experienced road builders upon this subject.

**Green fodder in winter** (*Sächs. Landw. Ztschr.*, 45 (1897), No. 41, pp. 563-566, figs. 3).—A description of a press useful in preserving forage crops.

**A model cow shed**, J. MAHON (*Queensland Agr. Jour.*, 1 (1897), No. 6, pp. 437, 438, pl. 1).—Drawings and specifications for a barn to accommodate twenty cows are given.

#### STATISTICS—MISCELLANEOUS.

**Agriculture in Alaska**, W. H. EVANS, B. KILLIN, and S. JACKSON (*U. S. Dept. Agr., Office of Experiment Stations Bul.* 48, pp. 36, pls. 23).—This bulletin is the report to Congress of the commission referred to in E. S. R., 9, p. 401. The general features of the investigation are given in that place.

The report gives the general topography and meteorology of the country, including comparative tables which show the average temperature and precipitation of Alaskan, North European, and Canadian stations. The soils of Alaska are discussed at some length and tables are given showing the percentage of coarse and fine earth and the mechanical analyses of 24 samples of soils and subsoils. The natural products of the country are discussed and analyses of the following grasses given: *Phleum pratense*, *Poa pratensis*, *Bromus* sp., *Anthoxanthum odoratum*, *Deschampsia botanica*, and *Calamagrostis aleutica*. Comparisons are made of these and similar species grown elsewhere. Notes are given on the cultivated products, which consist almost entirely of garden crops. The possible extent of agriculture, as shown by the area of arable lands, is indicated and some of the difficulties and possibilities pointed out. A list of about 100 economic plants and various notes on the native animals and industries are given.

In the preliminary report of Sheldon Jackson brief notes are given on his observations made along the Yukon River as far as Dawson. At various points visited hardy vegetables were seen growing, and grasses taller than a man are reported as growing abundantly.

**Tenth Annual Report of Colorado Station, 1897** (*Colorado Sta. Rpt. 1897, pp. 110*).—This contains a financial statement for the fiscal year ending June 30, 1897; the station organization list; inventory of station property; text of the Hatch Act; brief extracts from Circular 29 of the Office of Experiment Stations and from the Report of the Secretary of Agriculture for 1897 (E. S. R., 9, pp. 298, 698); subject list of station Bulletins 1-40; a quite lengthy report by the director, dealing largely with the present status of the station and substations, financially and otherwise, and the interrelationship of the college and station; and short reports by the agriculturist, botanist and horticulturist, chemist, entomologist, meteorologist, and irrigation engineer (see p. 1095), and the superintendents of the substations at Arkansas Valley and Cheyenne Wells. The reports of the substations deal principally with tests of various crops and varieties of fruits, vegetables, etc. A brief note is also given on the use of cornstalks as windbreaks for crop protection.

**Ninth Annual Report of Kentucky Station, 1896** (*Kentucky Sta. Rpt. 1896, pp. XLIII, Append. pp. 114*).—Organization list; report of the treasurer for the fiscal year ending June 30, 1896; brief report by the director on the staff, equipment, publications, etc., of the station; reports by the heads of the departments of chemistry, entomology, botany, horticulture, and meteorology, on the work of the year, detailed results being given in some instances (noted elsewhere); reprints of Bulletins 61-65 of the station; and an index to the report and bulletins.

**Annual Report of South Carolina Station, 1897** (*South Carolina Sta. Rpt. 1897, pp. 24*).—Includes the organization list of the station, text of the Hatch Act of March 2, 1887, and brief reports by the vice-director and heads of departments on the work of the year, with a list of the bulletins published. In addition to the general work of the chemist, the results of analyses of two samples of Sea Island cotton seed, a summary of the results of fertilizer inspection in the State during 1896 and 1897, and notes and comments on the sanitary examination of a number of artesian well and spring waters are given.

**Annual Report of Virginia Station, 1897** (*Virginia Sta. Rpt. 1897, pp. 12*).—This contains the organization list, subject list of bulletins published during the year, treasurer's report for the fiscal year ending June 30, 1897, and short reports on the work of the year by the heads of the different departments. The report of the meteorologist included within these pages is noted on page 1034.

**A report on the work and expenditures of the agricultural experiment stations, 1897**, A. C. TRUE (*U. S. Dept. Agr., Office of Experiment Stations Bul. 50, pp. 97, figs. 6*).—A critical review of the conduct and general management of the stations, with brief abstracts of all station publications received by the Office of Experiment Stations during the fiscal year ending June 30, 1897; and general statistics of the stations relative to organization, publications, principal lines of work, revenue, etc.

**Report of the work during 1896 at the agricultural station of the Island of Mauritius**, P. BONAME (*Ann. Sci. Agron., 1897, II, No. 2-3, pp. 307-358*).

**Report of the Royal Society for Norway's Weal for 1896** (*Christiania, 1897, pp. 160*).

**Agriculture in Denmark compared with that in Great Britain**, H. NATHORST (*Tidskr. Landtmän, 18 (1897), No. 37, pp. 668-673*).

**Activities of agricultural associations in the past, present, and future**, N. HEYMANN (*Tidsskr. Landökon., 16 (1897), No. 5-6, pp. 417-458*).

**Agricultural conditions on the Island of Jersey**, J. LARSEN (*Tidsskr. Landökon., 16 (1897), No. 5-6, pp. 479-489*).

**Agricultural calendar for 1898**, K. K. HEJE (*Lomme-Almanak for Landmænd, Mejerister og Skogbrugere, 1898. Christiania, 1897*).

**Land economic associations in Denmark**, J. C. LA COUR (*Tidsskr. Landökon. 16 (1897), No. 5-6, pp. 459-478*).

**Organization lists of the agricultural experiment stations and institutions with courses in agriculture in the United States** (*U. S. Dept. Agr., Office of Experiment Stations Bul. 47, pp. 96*).—In addition a subject list of publications of the

experiment stations received by the Office of Experiment Stations during 1897, and the Federal legislation relating to the colleges and stations and the rulings of the Treasury, Post-Office, and Agricultural Departments as to the construction of the act of Congress of March 2, 1887, establishing the stations, are included.

**Truth about agricultural depression; an economic study of the evidences of the Royal Commission,** F. A. CHANNING (*London: Longmans Green & Co., 1897, pp. 388*).—The author sums up and analyzes the data accumulated by the recent Royal Commission appointed to investigate the causes of agricultural depression in England. The history of the decline of British agriculture, past and present methods of farming, economic relationship of landlords and tenants, etc., are discussed at length. Excessive rents is believed to be the chief cause of the depression.

**Agricultural statistics of the province of South Australia, 1896** (*South Australia Stat. Reg., 1897, pt. 3, pp. 83*).—This gives returns showing the total acreage of occupied and cultivated land, acreage of each of the different farm and orchard crops and the produce therefrom, stands of bees and the honey product, number and kinds of live stock, wool production, etc., of each district and county of the Province for the year ending March 31, 1897. The number of mills and manufactories, rates of wages, prices of raw and manufactured product, etc., are also given. In some instances similar data are given for preceding years for comparison.

**Statistics of the land-grant colleges and agricultural experiment stations in the United States** (*U. S. Dept. Agr., Office of Experiment Stations Bul. 51, pp. 39*).—A summary of the data contained in this bulletin has already appeared (*E. S. R., 9, p. 701*).

**Proceedings of the eleventh annual convention of the Association of American Agricultural Colleges and Experiment Stations,** A. C. TRUE and H. H. GOODSELL (*U. S. Dept. Agr., Office of Experiment Stations Bul. 49, pp. 100, fig. 1*).—This gives the officers and committees of the Association and the proceedings of the convention held at Minneapolis, Minn., July 13–15, 1897, an account of which has already appeared (*E. S. R., 9, p. 303*). In addition to the general business and discussions the following papers are included: Evolution of agricultural education, G. T. Fairchild; Advertising in Experiment Station publications, A. C. True; An experiment, its conception and methods of procedure, H. L. Bolley; How may university extension work be best conducted by the colleges of agriculture, I. P. Roberts; Preparatory teaching in agricultural colleges, E. W. Hilgard; Preparatory work in agricultural colleges, W. M. Hays; Science vs. art, I. P. Roberts; Methods of keeping records of horticultural work at the State Agricultural Experiment Station, Geneva, N. Y., S. A. Beach; The importance of mycophagy in a course on botanical instruction, H. N. Starnes; Classification of varieties of peaches, R. H. Price; Horticultural education in Minnesota, S. B. Green; A bacterial disease of cabbage and allied plants, H. L. Russell; Development of electrical engineering in Utah, J. Jensen; and A calorimetric determination of the heating value of corn, C. R. Richards.

**Teaching agriculture and the sciences,** O. PAVETTE (*L'enseignement des sciences et de l'agriculture. Paris: Fernand Nathan, 1898, pp. 36*).—A revised edition for the use of instructors.

**The new chemical institute of the University of Breslau,** SCHOLTZ and KLINGENSTEIN (*Chem. Ztg., 21 (1897), No. 51, pp. 501–503, figs. 3*).

**Public laboratory and experiment station in Johannesburg (South African Republic),** J. LOEVY (*Chem. Ztg., 21 (1897), No. 69, pp. 677, 678, fig. 1*).—A plan and description of the new building opened in May, 1897.

**Report of the chemical and seed control station at Skara, 1896,** O. NYLANDER (*Skara (Sweden), 1897, pp. 16*).

**On government control of fertilizers, feeding stuffs, and seeds in Sweden** (*Landtmannen, 8 (1897), Nos. 18, pp. 243–247; 19, pp. 259–264*).

**The chemical plant biological station at Luleå, Sweden** (*Landtmannen, 8 (1897), No. 6, pp. 71–76*).

## NOTES.

---

IDAHO STATION.—The citizens of Moscow have recently donated to the station 10 acres of land additional to the tract already given, making 94 acres in all. The new tract is so situated as to add greatly to the value and convenience of the station farm. Contracts for material have been made for a greenhouse, with work rooms and class room.

MICHIGAN STATION.—A. A. Crozier has resigned his position as agriculturist of the station, and J. D. Towar, formerly of the Rhode Island College and Station, has been appointed field agriculturist.

A systematic series of soil examinations begun last year will continue through this season under the supervision of M. W. Fulton, the object being to study the relation of the soil to water.

MONTANA COLLEGE AND STATION.—Robert S. Shaw has been appointed professor of agriculture in the college and assistant agriculturist of the station.

NORTH CAROLINA STATION.—J. D. Hufham, jr., assistant chemist; S. B. Moore, clerk; and L. W. Physioc, mailing clerk, have severed their connection with the station; and the following appointments have been made: Mrs. L. V. Darby, stenographer, and C. M. Hughes, clerk. F. G. Kelly has been changed from clerk to assistant chemist.

SOUTH CAROLINA STATION.—J. S. Pickett has been made foreman of the station farm. The station barn, burned by lightning August 5, 1897, has been replaced by a large storage barn for dry fodder, silos, and motive-power machinery; a dairy barn with a capacity for 52 cows; and a general purpose barn, the first floor of which is used for stock and contains an office, milk room, feed bins, etc., and the second floor for general experimental work, with seed rooms, etc. The poultry division has established 36 pens 20 by 36 ft. and 9 runs 80 by 150 ft., all of which is inclosed with the most improved poultry cable and picket wire.

PERSONAL MENTION.—Dr. George Henry Horn, born at Philadelphia, April 7, 1840, died at Busleys Point, New Jersey, December 24, 1897. Dr. Horn's works on North American Coleoptera are well known. In his 150 more important contributions to entomology and in minor notes he named 150 new genera and more than 1,550 new species, very few of which are now classed as synonyms.

Dr. Askenasy has become honorary professor of botany at Bonn.

# EXPERIMENT STATION RECORD.

VOL. IX.

No. 12.

The present number completes the ninth volume of the Record. The character and extent of the work in this and the preceding volume is indicated by the following table:

	Volume VIII.	Volume IX.
Station reports.....	62	56
Station bulletins.....	340	317
Publications of United States Department of Agriculture.....	92	201
Foreign articles.....	702	842
Total number of articles.....	1,565	1,810
Classified as follows:		
Chemistry.....	157	121
Botany.....	69	86
Fermentation and bacteriology.....	5	28
Zoology.....	10	31
Meteorology.....	54	57
Water and soils.....	55	72
Fertilizers.....	103	85
Field crops.....	228	153
Horticulture.....	154	138
Forestry.....	11	16
Seeds and weeds.....	29	41
Diseases of plants.....	79	107
Entomology.....	126	252
Foods and animal production.....	177	186
Dairy farming and dairying.....	139	151
Veterinary science.....	51	134
Technology.....	4	11
Agricultural engineering.....	22	38
Statistics.....	92	103

The abstracts in this volume occupy 770 pages, and required in their preparation the reviewing of 56,569 pages in the original publications. In addition to this the volume contains 2,471 titles (mostly foreign), not abstracted; 14 editorials, occupying 30 pages; 8 special articles, occupying 136 pages, and 93 station notes, occupying 11 pages.

As in previous volumes the subject-index has been made in sufficient detail to serve as a fairly complete guide to the contents of the publications abstracted.

The review of the literature of agricultural science made in this volume of the Record is more complete than heretofore. Especial attention has been given of late to extending the range of the abstracts in a number of subjects, and especially in veterinary science. The Russian and Italian reports of agricultural investigations have also been more thoroughly reviewed. The task of collecting and abstracting the books, periodicals, and miscellaneous publications in which the

records of agricultural science are printed becomes larger and more difficult each year. While we have received much assistance from publishers and authors in our efforts to secure material for the Record, we still need the further cooperation of our readers, especially to bring to our attention articles which are first published in out of the way places. It is recognized that the Record might well be developed in the direction of adding at least brief abstracts to all the titles recorded. Our present force of workers will permit little, if any, expansion in the amount of matter prepared for publication. It is a fact to be deplored that from time to time long articles of much importance are passed over with only a brief notice because of the time required to make a satisfactory review of them. We are, however, encouraged by the increasing testimony regarding the value of a comprehensive review of the current literature of agricultural science to make renewed efforts to make our work in this line still more complete and satisfactory.

## INDEX OF NAMES.

## INDEX OF SUBJECTS.

	Page		Page.
Aberrations in <i>Vanessa antiopa</i> .....	965	Agar cultures of algæ and amœba .....	29
<i>Abies balsamea</i> as affected by <i>Ecidium clati-</i>		preparation .....	628
<i>num</i> .....	421	for bacteriological examination of	
<i>shastensis</i> , notes .....	52, 651	water .....	924
Abietinæ, formation of resin deposits.....	452	<i>Agaricus arvensis</i> , notes, U. S. D. A .....	649
<i>Ablerus clisicampe</i> , notes, U. S. D. A .....	663	<i>campestris</i> , notes .....	526
Abortion in domestic animals.....	292	U. S. D. A .....	649
infectious, of cattle .....	293	<i>Agelæus phœnicus</i> , notes, U. S. D. A .....	670
sheep, Iowa .....	994	Agglutination of <i>Bacillus typhosus</i> .....	692
Absorption in small intestine.....	1079	phenomena and the cholera	
Acacia pod moth, notes .....	768	vibrio .....	392
<i>Acantho-inus nodosus</i> , notes, U. S. D. A .....	669	in glanders.....	391
Acari, agrarian .....	966	Agricultural—	
Acarids of wine.....	895	and dairy institute of Mustiala, report.	298
<i>Accipiter nisus</i> , notes .....	530	appropriation bill.....	901
Acclimation of plants .....	1028	associations in Belgium.....	3
Acclimatization in Russia .....	726	the past, present, and	
<i>Acer californicum</i> , notes .....	563	future.....	1098
<i>Achæa melicerata</i> , notes.....	768	calendars .....	599, 1098
<i>Achillea</i> , species .....	561, 756	Chemists, Association of Official.....	226, 404
Acid in beer, determination.....	918	chemistry, progress .....	115
phosphate, analyses, La .....	1044	college and experiment station work...	301
Mass. Hatch.....	939	colleges and experiment stations, Fed-	
Vt.....	336, 825	eral legislation, U. S. D. A .....	1999
vs. raw bone meal for cot		courses in, U. S. D. A .....	297
ton, Ga.....	127	domestic science in .....	479
Acidimetry method for approximate de-		statistics.....	701

## U. S. DEPARTMENT OF AGRICULTURE.

### *Scientific Bureaus and Divisions.*

WEATHER BUREAU—Willis L. Moore, *Chief.*

BUREAU OF ANIMAL INDUSTRY—D. E. Salmon, *Chief.*

DIVISION OF STATISTICS—J. Hyde, *Statistician.*

DIVISION OF ENTOMOLOGY—L. O. Howard, *Entomologist.*

DIVISION OF CHEMISTRY—H. W. Wiley, *Chemist.*

DIVISION OF BOTANY—F. V. Coville, *Botanist.*

DIVISION OF FORESTRY—B. E. Fernow, *Chief.*

DIVISION OF BIOLOGICAL SURVEY—C. Hart Merriam, *Biologist.*

DIVISION OF POMOLOGY—G. B. Brackett, *Pomologist.*

DIVISION OF VEGETABLE PHYSIOLOGY AND PATHOLOGY—B. T. Galloway, *Chief.*

DIVISION OF SOILS—M. Whitney, *Chief.*

DIVISION OF AGROSTOLOGY—F. Lamson-Scribner, *Chief.*

OFFICE OF EXPERIMENT STATIONS—A. C. True, *Director.*

### THE AGRICULTURAL EXPERIMENT STATIONS.

ALABAMA—*Auburn*: College Station; W. L. Brown.† *Uniontown*: Canebrake Station; H. Benton.‡

ARIZONA—*Tucson*: W. S. DeVol.\*

ARKANSAS—*Fayetteville*: R. L. Bennett.\*

CALIFORNIA—*Berkeley*: E. W. Hilgard.\*

COLORADO—*Fort Collins*: Alston Ellis.\*

CONNECTICUT—*New Haven*: State Station; S. W. Johnson.\* *Storrs*: Storrs Station; W. O. Atwater.\*

DELAWARE—*Newark*: A. T. Neale.\*

FLORIDA—*Lake City*: W. F. Yocum.\*

GEORGIA—*Experiment*: R. J. Redding.\*

IDAHO—*Moscow*: F. B. Gault.\*

ILLINOIS—*Urbana*: E. Davenport.\*

INDIANA—*Lafayette*: C. S. Plumb.\*

IOWA—*Ames*: C. F. Curtiss.\*

KANSAS—*Manhattan*: Thos. E. Will.‡

KENTUCKY—*Lexington*: M. A. Scovell.\*

LOUISIANA—*Audubon Park, New Orleans*: Sugar Station. *Baton Rouge*: State Station. *Calhoun, North Louisiana* Station. W. C. Stubbs.\*

MAINE—*Orono*: C. D. Woods.\*

MARYLAND—*College Park*: R. H. Miller.\*

MASSACHUSETTS—*Amherst*: H. H. Goodell.\*

MICHIGAN—*Agricultural College*: C. D. Smith.\*

MINNESOTA—*St. Anthony Park*: W. M. Liggett.\*

MISSISSIPPI—*Agricultural College*: W. L. Hutchison.\*

MISSOURI—*Columbia*: H. J. Waters.\*

MONTANA—*Bozeman*: S. M. Emery.\*

NEBRASKA—*Lincoln*: G. E. MacLean.\*

NEVADA—*Reno*: J. E. Stubbs.\*

NEW HAMPSHIRE—*Durham*: C. S. Murkland.‡

NEW JERSEY—*New Brunswick*: E. B. Voorhees.\*

NEW MEXICO—*Mesilla Park*: C. T. Jordan.\*

NEW YORK—*Geneva*: State Station; W. H. Jordan.\* *Ithaca*: Cornell University Station; I. P. Roberts.\*

NORTH CAROLINA—*Raleigh*: W. A. Withers.‡

NORTH DAKOTA—*Agricultural College*: J. H. Worst.\*

OHIO—*Wooster*: C. E. Thorne.\*

OKLAHOMA—*Stillwater*: G. E. Morrow.\*

OREGON—*Corvallis*: T. S. Gatch.\*

PENNSYLVANIA—*State College*: H. P. Armsby.\*

RHODE ISLAND—*Kingston*: J. H. Washburn.‡

SOUTH CAROLINA—*Clemson College*: H. S. Hartzog.\*

SOUTH DAKOTA—*Brookings*: J. H. Shepard.\*

TENNESSEE—*Knoxville*: C. F. Vanderford.‡

TEXAS—*College Station*: J. H. Connell.\*

UTAH—*Logan*: L. Foster.\*

VERMONT—*Burlington*: J. L. Hills.\*

VIRGINIA—*Blacksburg*: J. M. McBryde.\*

WISCONSIN—*Madison*: W. A. Henry.\*

WYOMING—*Laramie*: F. P. Graves.\*

\* Director.

† President of board of direction.

‡ Assistant director in charge.

§ Chairman of council.

¶ Secretary.

‡ Acting director.

## PUBLICATIONS OF THE OFFICE OF EXPERIMENT STATIONS.

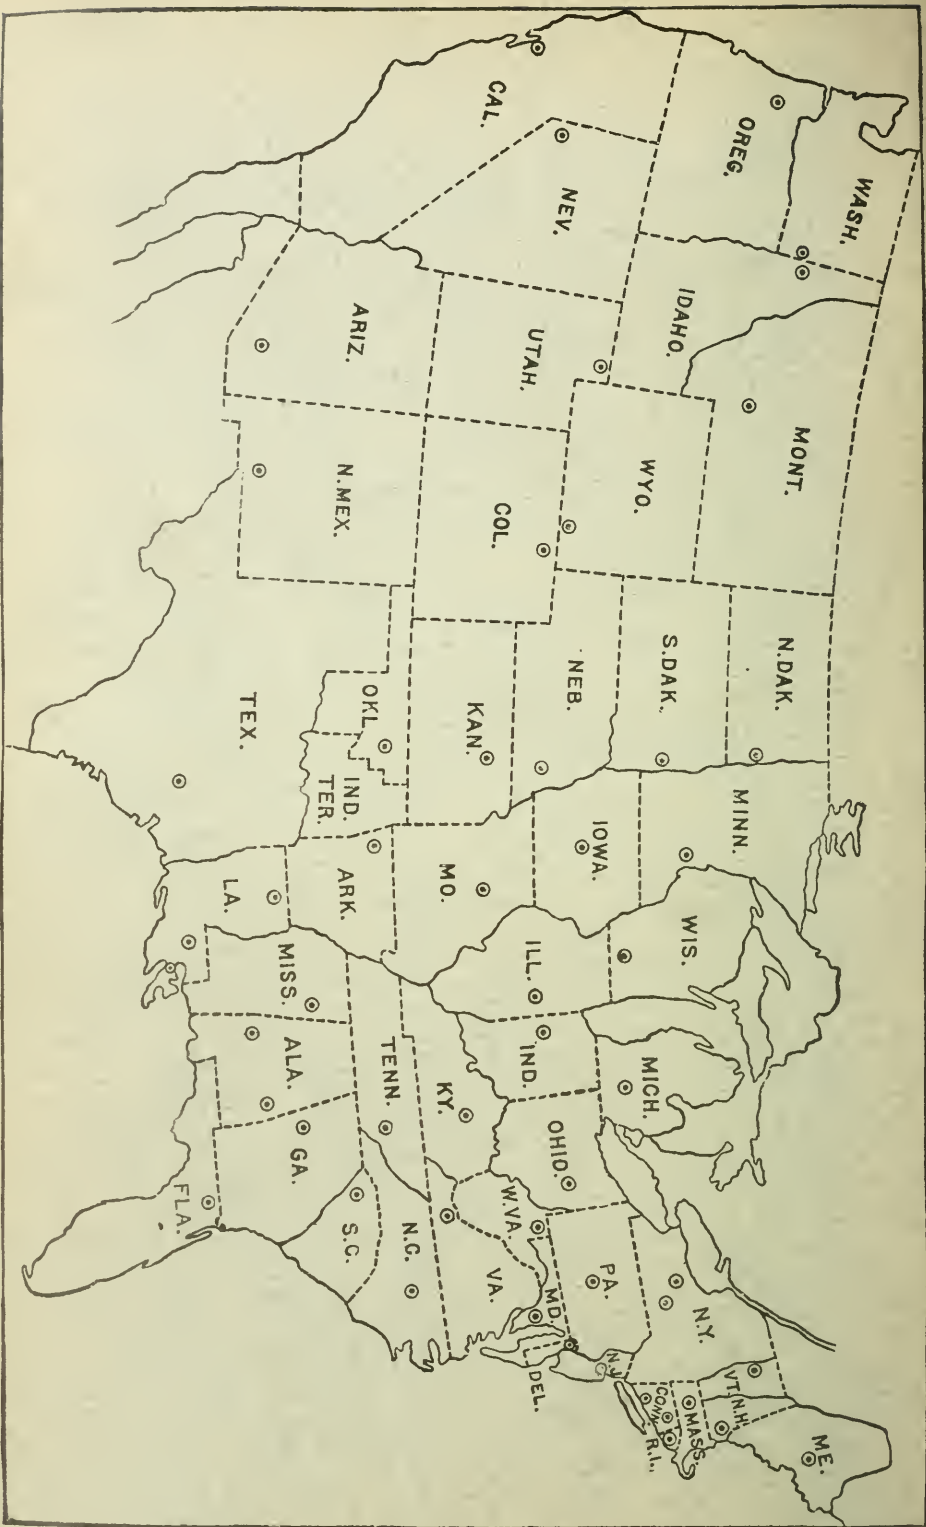

*Experiment Station Record*, Vols. I to VIII, with indexes; Vol. IX, Nos. 1-3.

*Bulletins*.—No. 1, Organization and History of the Stations; No. 2, Digest of Annual Reports of the Stations for 1888, in two parts; No. 3, Report of Meeting of Horticulturists, 1889; No. 4, List of Station Horticulturists and Outline of their Work; No. 5, Organization Lists of Stations and Colleges, 1890; No. 6, List of Station Botanists and Outline of their Work; No. 7, Proceedings of Association of Agricultural Colleges and Experiment Stations, 1891; No. 8, Lectures on Investigations at Rothamsted Experimental Station; No. 9, The Fermentations of Milk; No. 10, Meteorological Work for Agricultural Institutions; No. 11, A Compilation of Analyses of American Feeding Stuffs; No. 12, Organization Lists of Stations and Colleges, 1892; No. 13, Organization Lists of Stations and Colleges, 1893; No. 14, Proceedings of Convention of National League for Good Roads, 1893; No. 15, Handbook of Experiment Station Work; No. 16, Proceedings of Association of Agricultural Colleges and Experiment Stations, 1892; No. 17, Suggestions for the Establishment of Food Laboratories; No. 18, Assimilation of Free Atmospheric Nitrogen by White and Black Mustard; No. 19, Organization Lists of Stations and Colleges, 1894; No. 20, Proceedings of Association of Agricultural Colleges and Experiment Stations, 1893; No. 21, Methods and Results of Investigations on the Chemistry and Economy of Food; No. 22, Agricultural Investigations at Rothamsted, England; No. 23, Organization Lists of Stations and Colleges, 1895; No. 24, Proceedings of Association of Agricultural Colleges and Experiment Stations, 1894; No. 25, Dairy Bacteriology; No. 26, Agricultural Experiment Stations: Their Objects and Work; No. 27, Organization Lists of Stations and Colleges, 1896; No. 28, The Chemical Composition of American Food Materials; No. 29, Dietary Studies at the University of Tennessee in 1895; No. 30, Proceedings of Association of Agricultural Colleges and Experiment Stations, 1895; No. 31, Dietary Studies at the University of Missouri in 1895; No. 32, Dietary Studies at Purdue University in 1895; No. 33, The Cotton Plant: Its History, Botany, Chemistry, Culture, Enemies, and Uses; No. 34, The Carbohydrates of Wheat, Maize, Flour, and Bread, and the Action of Enzymic Ferments upon Starches of Different Origin; No. 35, Food and Nutrition Investigations in New Jersey in 1895 and 1896; No. 36, Notes on Irrigation in Connecticut and New Jersey; No. 37, Dietary Studies at the Maine State College in 1895; No. 38, Dietary Studies with Reference to the Food of the Negro in Alabama in 1895 and 1896; No. 39, Organization Lists of Stations and Colleges, 1897; No. 40, Dietary Studies in New Mexico in 1895; No. 41, Proceedings of Association of Agricultural Colleges and Experiment Stations, 1896; No. 42, Cotton Culture in Egypt; No. 43, Losses in Boiling Vegetables, and the Composition and Digestibility of Potatoes and Eggs; No. 44, Report of Preliminary Investigations on the Metabolism of Nitrogen and Carbon in the Human Organism, with a Respiration Calorimeter of Special Construction.

*Miscellaneous Bulletins*.—Nos. 1, 2, and 3, Proceedings of Association of Agricultural Colleges and Experiment Stations, January and November, 1889, and November, 1890. (Series discontinued.)

*Farmers' Bulletins*.—No. 1, The What and Why of Agricultural Experiment Stations; No. 2, Illustrations of the Work of the Stations; No. 9, Milk Fermentations and their Relation to Dairying; No. 11, The Rape Plant; No. 14, Fertilizers for Cotton; No. 16, Leguminous Plants for Green Manuring and for Feeding; No. 18, Forage Plants for the South; No. 21, Barnyard Manure; No. 22, The Feeding of Farm Animals; No. 23, Foods: Nutritive Value and Cost; No. 25, Peanuts: Culture and Uses; No. 26, Sweet Potatoes: Culture and Uses; No. 29, Souring of Milk and Other Changes in Milk Products; No. 32, Silos and Silage; No. 34, Meats: Composition and Cooking; No. 35, Potato Culture; No. 36, Cotton Seed and its Products; No. 37, Kafir Corn: Characteristics, Culture, and Uses; No. 39, Onion Culture; No. 41, Fowls: Care and Feeding; No. 44, Commercial Fertilizers: Composition and Use; No. 46, Irrigation in Humid Climates; No. 48, The Manuring of Cotton; No. 49, Sheep Feeding; No. 56, Experiment Station Work—1.
